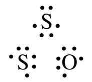
Sulfur-Oxygen Compounds. Due to its $3s^2 3p^4$ electron configuration sulfur, like oxygen, forms many divalent compounds with two covalent bonds and two lone electron pairs, but d-hybridization is quite common, to form compounds with oxidation of 4+ and 6+.

A number of suboxides of sulfur have been reported, but in general their composition has not been clearly established. Polysulfur oxides of formula $S_{8-16}O_2$ are formed by reaction of hydrogen sulfide and sulfur dioxide. Also, when sulfur is burned with oxygen in very limited supply disulfur monoxide, S_2O is formed. This has the structure



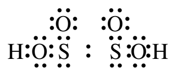
A mixture of sulfur dioxide, SO_2, and sulfur vapor, at low pressure and with an electric discharge, forms sulfur monoxide, SO. Its presence is shown from its absorption spectrum, but upon separation it disproportionates at once to sulfur and SO_2. Sulfur sesquioxide, S_2O_3, is formed by reaction of powdered sulfur with anhydrous SO_3; S_2O also disproportionates (at 20°C in nitrogen) to sulfur and SO_2. Sulfur dioxide, SO_2, is

formed by the combustion in air or oxygen of sulfur and sulfur compounds generally, except those in which sulfur is in a higher state of oxidation. Sulfur dioxide has an O—S—O bond angle of 119.5°. The sigma bonds utilize essentially sulfur *p* orbitals, with *dp* hybridization for the pi bonds. Its oxidation to sulfur trioxide, SO_3, by atmospheric oxygen attains a significant rate only at higher temperatures, but can be materially increased by catalysts. Sulfur trioxide is also evolved from oleum on heating. It exists in the vapor state chiefly as the planar monomer, in which the oxygen atoms are spaced symmetrically (120° angles) about the sulfur atom, and it has S—O bond lengths of 1.43 Å. Liquid SO_3 is partly trimerized, and exists in three physical forms.

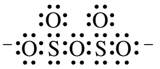
Sulfur tetroxide is formed by reaction of pure oxygen and sulfur dioxide under the silent electric discharge. It is not obtained pure, but in a variable SO_3/SO_4 ratio, and as a polymerized white solid. Another peroxide, $(SO_2OOSO_2O)_x$, which is written as S_2O_7, is known.

Of the 16 oxyacids of sulfur that are recognized, only four have been isolated. The more important oxyacids of sulfur are: (1) Thiosulfurous acid, $H_2S_2O_2$, structure not established, existing only in compounds, an oxidizing agent for Fe^{2+}, H_2S and HI; (2) Sulfoxylic acid, H_2SO_2, existing only in salts and other compounds, e.g., $ZnSO_2$, SCl_2, $S(OR)_2$, structure probably

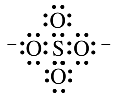
(3) Dithionous acid (or hydrosulfurous acid), $H_2S_2O_4$, existing only in compounds, widely used reducing agent, chiefly as the sodium salt, for organic substances, also reduces Sb^{3+}, Ag^+, Pb^{2+}, Cu^{2+} to the elements, structure



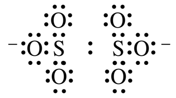
(4) Sulfurous acid, H_2SO_3, produced by hydration of SO_2, not isolated but existing in many salts, the sulfites and acid sulfites, and many organic compounds, including the dialkyl or diaryl sulfites and the alkyl or aryl sulfonic acid esters, which suggests two possible structures, $(HO)_2SO$ and $H(HO)SO_2$, although the acid dissociation constants (first, 1.25×10^{-2}, and second, 5.6×10^{-8}) suggest the structure with only one unhydrogenated oxygen atom. Sulfurous acid and sulfites are fairly strong reducing agents, but the HSO_3^- ion may act as an oxidizing agent, as for formates and related compounds. Other compounds of SO_2 are the metabisulfites or pyrosulfites, containing the ion



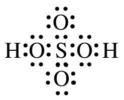
which enters into equilibrium with water to form acid sulfite. (5) Thiosulfuric acid, $H_2S_2O_3$, existing only in compounds, the anion having the structure



and widely used as a coordinating ion for forming complexes with metals; it also is an oxidizing agent, and is used in iodometric titrations. (6) Dithionic acid, $H_2S_2O_6$, existing only in compounds but stable in dilute solution at room temperature, and differing in its stability to hydrolysis and oxidation from the polythionates,



(7) Polythionic acids, $H_2S_nO_6$, in which n has values of 3, 4, 5, 6 and others, some of which have been reported to have values indefinitely high (20–80), structure not established, though there is evidence that they consist of two sulfonic acid groups connected by a linear chain of sulfur atoms. An interesting property of the polythionates that are very rich in sulfur ($n > 20$) is their slight tendency to decompose to give free S. (8) Sulfuric acid, H_2SO_4, structure



strong acid, formed by hydration of sulfur trioxide, completely dissociated (first ionization) in aqueous solutions up to 40%; above that concentration dissociation decreases and hydrate formation occurs. Both normal and acid sulfates are formed by metallic elements, though the products of their direct reaction with the acid vary with temperature. (9) Sulfuric acid dissolves SO_3, the product of a 1:1 ratio being pyrosulfuric or disulfuric acid. $H_2S_2O_7$, which forms the pyrosulfates, also obtainable by heating acid sulfates, structure HO(O)(O)SOS(O)(O)OH. Two series of alkali metal pyrosulfates are known: those formed from SO_3 and the metal sulfates and those formed from H_2SO_4 and the metal sulfates, which have the pyrosulfuric acid structure. (10) Peroxymonosulfuric acid is produced by addition of SO_3 to concentrated H_2O_2, its salts are fairly stable, and it has the structure HOS(O)(O)OOH. (11) Peroxydisulfuric acid is produced by reaction of concentrated H_2O_2 on H_2SO_4 or by electrolysis of acid sulfate solutions; its salts are fairly stable and it has the structure HOS(O)(O)OOS(O)(O)OH.

Hydrogen Sulfide. H_2S is a weak acid ($pK_{A1} = 7.00$), ($pK_{A2} = 12.92$) stronger than water but weaker than H_2Se, as expected from its position in the periodic system; its reducing strength exhibits the same relation. Its long use in analytical chemistry is due to the differential solubility of many sulfides with variation of the pH of an aqueous solution. Hydrogen persulfide, H_2S_2, structure HSSH, with an S—S bond distance of 2.05 Å, formed from an alkali metal polysulfide solution and HCl at low temperatures, is the first of a group of hydrogen polysulfides of the general formula H_2S_x.

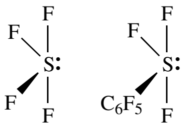
Sulfur Halides. Many are known. Those that have been identified and whose properties have been determined include the fluorine compounds, S_2F_2, SF_4, SF_6, S_2F_{10}, the chlorine compounds, S_2Cl_2, SCl_2, SCl_4 and the bromine compound, S_2Br_2. Sulfur chlorides of general formula S_nCl_2 are known up to $n \approx 20$. A similar series of cyanides, $S_n(CN)_2$, is known. Derivatives of SCl_4, e.g., SCl_3CN, have been prepared and the list of derivatives of SF_6 is rapidly growing, including S_2F_{10}, $(SF_5)_2O$, $(SF_5)_2O_2$, SF_5Cl, SF_5Cl_3, $SF_4(CF_3)_2$, $(SF_5)_2CF_2$, SF_5OF, SF_5OSO_2F, etc. Derivatives of SF_4 include $C_6H_5SF_3$, $(SF_3)_2CF_2$, etc. All of them except the higher fluorides hydrolyze readily, and they are essentially covalent in character. The simple compounds can be prepared directly from the elements, the activity of the halogen determining the product obtained: fluorine yielding SF_6 and S_2F_{10} and the other fluorides being prepared from those; chlorine and bromine yielding the monohalides, from which the others are obtained by continued halogenation.

Sulfur Oxyhalides. Four general compositions of oxyhalides of sulfur have been known for many years. In one of these, sulfur has a 4+ oxidation state, the thionyl halides, SOX_2, and in three of which it has a 6+ oxidation state, thionyl tetrafluoride, the sulfuryl and pyrosulfuryl halides, SOF_4, SO_3X_2 and $S_2O_5X_2$, respectively. As is the case for the simple halides, no iodine compounds are known, but polyhalogen ones, such as SOFCl and SO_2FCl exist.

Isolable Oxysulfuranes. Sulfuranes, as described by Musher (1969), are compounds of sulfur(IV) in which four ligands are attached to sulfur and have in common with rare-gas compounds such as XeF_2 an electronic structure involving a formal expansion of the valence shell of the central atom from 8 to 10 electrons. Martin and Perozzi (1976) pointed out that the incorporation of oxygen ligands makes possible a wide range of new structural types that illustrate structure-reactivity relationships in a particularly illuminating way.

For many years, it was postulated that most types of sulfuranes were intermediate (not isolable) compounds. However, the isolable halosulfuranes have been well established for many years. The first known of these, SCl_4, was prepared by Michaelis and Schifferdecker in 1873. In 1911, it was found that SF_4, while highly reactive, was thermally stable. However, the compound was not fully described until 1929. Development of SF_4 led to the creation of a family of stable fluorosulfuranes and their derivatives. It was found that the fluorines in these compounds can be replaced by aryl or perfluoroalkyl groups (Tyczkowski, 1953). Kimura and Bauer (1963) described the geometry of SF_4 as a distorted trigonal bipyramid with two fluorines and a lone pair of electrons occupying equatorial positions, with the other two fluorines in apical positions. The

postulated structures of SF_4 (a), and of a derivative (b) are shown below:

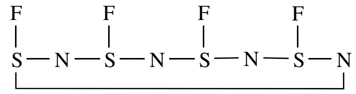


(**a**) (**b**)

In the early 1970s, Sheppard, by reacting SF_4 with pentafluorophenyllithium, prepared an isolated sulfurane with four carbon-centered ligands, namely, *tetrakis*-(pentafluorophenyl)sulfurane, $(C_6F_5)_4S$. Martin and Perozzi (1976) prepared the first isolable diaryldialkyloxysulfurane. If it is protected against moisture, the researchers found the compound to be stable over an indefinite period at room temperature. The research in this interesting area continues, some of the details of which are well described by Martin–Perozzi (1976). Summarizing the situation, the researchers observe that the development of synthetic methods for oxysulfuranes has made a wide range of isolable compounds of hypervalent sulfur available for study. Structure-reactivity correlations are now becoming evident as a result of such study. The fact that oxygen is dicoordinate makes it possible to sythesize cyclic oxysulfuranes and to use the pronounced changes of reactivity which accompany cyclization to design new, potentially useful sulfurane reagents stable enough to allow isolation.

Sulfur-Nitrogen Compounds. Many of the sulfur-nitrogen compounds are sulfuric acid derivatives. Three of these compounds correspond to replacement of the hydrogen atoms of ammonia with one, two and three—SO_3H radicals, the monosubstituted compound being aminesulfonic (sulfamic) acid, and being readily separated, the others known only in their salts, the aminedisulfonates (imidodisulfonates) and aminetrisulfonates (nitrilotrisulfonates). Other amines, such as hydroxylamine and hydrazine have similarly related compounds. See also **Hydrazine**; and **Hydroxylamine**. Diamino derivatives of the sulfoxy acids are also known, such as sulfamide, $H_2NSO_2NH_2$. Imidosulfinamide, HN $(SONH_2)_2$, has been prepared by reaction of $SOCl_2$ and ammonia (also directly from SO_2 and ammonia), and a trimer of sulfimide, $(O_2SNH)_3$, by ammoniation of SO_2Cl_2. It is cyclic in structure, composed of alternate >NH and >SO_2 groups. Nitrosulfonates, containing the ion $SO_3\ NO^-$ and dinitrososulfonates, containing $SO_3N_2O_2{}^{2-}$, are also known.

The most important sulfur-nitrogen compound is tetrasulfur tetranitride, S_4N_4, prepared in many ways, including the direct reaction of ammonia and sulfur. All data on its structure are in accord with a puckered eight-member ring, or a cage with N—S connections. The question as to whether there are also transannular N—N or S—S bonds has not been clearly settled. On hydrogenation it adds 4 H atoms, on fluorination it forms $S_4N_4F_4$, structure



and SN_2F_2 the latter reacting with SNF to form SNF_3, structure F_2SNF. Other thiazyl compounds, prepared from S_4N_4 and the halogens or sulfur halides, include $(ClSN)_3$, S_4N_3Cl, S_4N_3Br, S_4N_3I. These last are salts, i.e., $[N_4S_3]X$, and salts of other anions can also be prepared. Other sulfur-nitrogen compounds known are SN_2, S_4N_2, S_5N_2, and S_2N_2, the last being formed by heating S_4N_4.

Thiocyanogen, $(SCN)_2$, is formed by treatment of a metal thiocyanate with bromine in an organic solvent. It reacts with organic compounds in a manner completely analogous to the free halogens, lying between bromine and iodine in oxidizing power. The alkali metal and alkaline earth metal thiocyanates are prepared by fusing the cyanides with sulfur, and the other metal thiocyanates, as well as the organic ones, are usually prepared from the alkali metal thiocyanates. Many selenium analogs of thio compounds can be made, including $SeSO_3$, SO_3Se^{2-}, SSe^{2-}, etc.

In addition to carbon disulfide (odorless when pure), carbon subsulfide, S=C=C=C=S, an evil-smelling red oil and carbon monosulfide, (CS_x), are known as well as COS, CSSe and CSTe. Because of its similarity to oxygen, and the reactivity of its acids, sulfur enters widely into organic compounds.

SULFURIC ACID. Infrequently termed "oil of vitriol," sulfuric acid, [CAS: 7664-93-9], H_2SO_4, is a colorless, oily liquid, dense, highly reactive, and miscible with water in all proportions. Much heat is evolved when concentrated sulfuric acid is mixed with water and, as a safety precaution to prevent spluttering, the acid is poured into the water rather than vice versa. Sulfuric acid will dissolve most metals. The concentrated acid oxidizes, dehydrates, or sulfonates most organic compounds, sometimes causing charring. There are numerous commercial and industrial uses for H_2SO_4 and these include the manufacture of fertilizers, chemicals, inorganic pigments, petroleum refining, etching, as a catalyst in alkylation processes, in electroplating baths, for pickling and other operations in iron and steel production, in rayon and film manufacture, in the making of explosives, and in nonferrous metallurgy, to mention only some of its numerous uses. Because of its wide use industrially, some economists over the years have included sulfuric acid consumption among their economic indicators.

Most countries with significant industrial activity and particularly in chemicals production will have significant capacities for making sulfuric acid. In some countries, H_2SO_4 is the leading chemical in terms of tonnage production. Depending upon suppliers, H_2SO_4 is commercially available in a number of strengths, ranging from 77.7% H_2SO_4 (60° Baumé, sp. gr. 1.71) through 93.2% H_2SO_4 (66° Baumé), 98% H_2SO_4, 99% H_2SO_4, and 100% H_2SO_4 (sp. gr. 1.84).

Fundamentally, there are two kinds of sulfuric acid plants: (1) those that use the dry gas (sulfur burning) process; and (2) those that use the wet gas process. In the first type, the raw materials are elemental sulfur and water. In the second type, the sulfur dioxide feed may come from a variety of sources, including metallurgical smelters (copper, zinc, lead, etc.), pyrite roasters, waste acid decomposition furnaces, and hydrogen sulfide burners. In these plants, the SO_2 gas stream enters the acid plant containing a large amount of water vapor. The gas is usually hot (260–430°C) and dusty, and also may contain a number of impurities, such as fluorides, that could harm the catalyst in the contact section of the plant. These incoming gases thus require cooling and purification in the series of scrubbers and electrostatic precipitators, followed by drying prior to entering the contact section of the plant.

In either type of plant, sulfur dioxide is converted to sulfur trioxide in the contact portion of the plant. The reaction $SO_2 + \frac{1}{2}O_2 \longrightarrow SO_3$ is effected by passing the SO_2 over a catalyst, usually vanadium pentoxide (V_2O_5). The catalyst in the converter vessel is usually in the form of small pellets and typically arranged in four layers. Provision is made for removal of the heat of reaction after each layer or stage. The catalyst may be used for a number of years with only a very moderate decrease in activity.

From this fundamental point, the sulfuric acid plant designer has a number of alternatives and options to consider. Two factors are of major import in sulfuric acid plant design today, namely, recovery

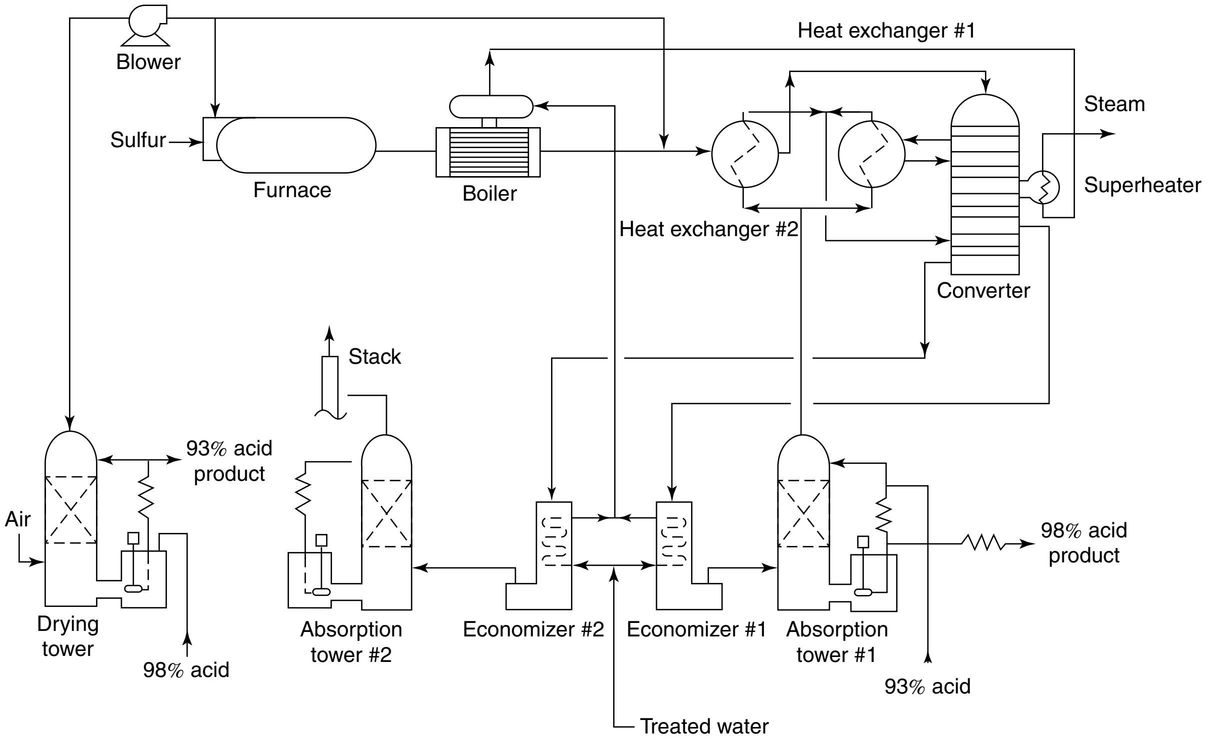

Fig. 1. Representative sulfuric acid plant of the sulfur-burning, double contact (DC), double absorption (DA) type

and conservation of energy, and minimizing environmental impact. For example, in the relatively simple plants of a few years age, the SO_2 need contact the catalyst but once and the absorption of the resulting SO_3 in water (a solution of sulfuric acid) could be handled in a single absorption tower. Recycling could be kept to a minimum. In the modern sulfuric acid plant, double contact (DC) of the gases with catalyst and double absorption (DA) of the gases is commonly practiced. Designs are available in numerous configurations, each offering various advantages in terms of energy conservation, pollution minimization, initial and operating costs. A typical sulfur-burning DC/DA sulfuric acid plant is shown in Fig. 1.

Of the approximately 40 million tons (36 million metric tons) of sulfuric acid manufactured in the United States per year, about 90% is used in the production of fertilizers and other inorganic chemicals. Much of the remaining 10% of H_2SO_4 is used by the petroleum, petrochemical, and organic chemicals industries. Much of this latter acid is involved in recycling kinds of processes. As pollution regulations in various countries become more restrictive, spent acid may become a much more attractive raw material than has been the case in the past.

As pointed out by Sander and Daradimos (1978), a regeneration of sulfuric acid of high quality can only be attained by thermal decomposition back to sulfur dioxide at high temperatures, where all organic impurities are completely burned—followed by reprocessing the SO_2 gases by the contact process to concentrated acid or oleum.

Reactivity of Sulfuric Acid

Dilute sulfuric acid reacts: (1) with many hydroxides, e.g., sodium hydroxide, to yield two series of sulfates (the acid is dibasic), e.g., sodium sulfate or sodium hydrogen sulfate, depending upon the ratio of acid to base reacting, (2) with many ordinary oxides, e.g., magnesium oxide, to yield the corresponding sulfate, e.g., magnesium sulfate solution, (3) with some carbonates, e.g., zinc carbonate, to yield the corresponding sulfate, e.g., zinc sulfate solution plus carbon dioxide gas (calcium carbonate is soon coated by a layer of calcium sulfate, which prevents further reaction), (4) with some sulfides, e.g., ferrous sulfide, to yield the corresponding sulfate, e.g., ferrous sulfate plus hydrogen sulfide gas, (5) with many metals, e.g., zinc, if not too pure (but not copper), to yield the corresponding sulfate, e.g., zinc sulfate solution plus hydrogen gas, (6) with solutions of some salts to yield the corresponding sulfate, e.g., barium chloride, changed to barium sulfate precipitate, calcium citrate, malate, tartrate to calcium sulfate precipitate and the free organic acid in solution.

Higher strengths of sulfuric acid react similarly in kind to the cases of (1), (2), (3), (6) above, but not, in general, as in cases (4) and (5) above. Copper and concentrated sulfuric acid yield copper sulfate and sulfur dioxide gas. Iron reacts similarly, yielding ferric sulfate in the place of copper sulfate.

A number of other reactions of sulfuric acid are characteristic of its higher strengths. Concentrated sulfuric acid is thus (7) an oxidizing agent, and a further example is the oxidation of sulfur to sulfur dioxide (the reacting sulfuric acid is reduced to sulfur dioxide), (8) a sulfonating agent, e.g., naphthalene sulfonated to naphthalene-sulfonic acids (mono-, alpha or beta, di- several), (9) an esterification agent, e.g., methyl alcohol esterified to dimethyl sulfate $(CH_3O)_2SO_2$, melting point $-32°C$, boiling point 189°C, or methyl hydrogen sulfate $CH_3O \cdot SO_2OH$, ethyl alcohol esterified to diethyl sulfate $(C_2H_5O)_2SO_2$, melting point $-26°C$, boiling point 208°C, or ethyl hydrogen sulfate $C_2H_5O \cdot SO_2OH$, (10) a dehydration agent, e.g., formic acid into carbon monoxide, sugar blackened with separation of carbon, (11) an addition agent, e.g., ethylene into ethyl hydrogen sulfate, (12) a nonvolatile acid upon heating, e.g., with sodium chlorite or nitrate, hydrogen chloride or nitric acid, respectively, is volatilized and sodium sulfate or sodium hydrogen sulfate remains as a residue.

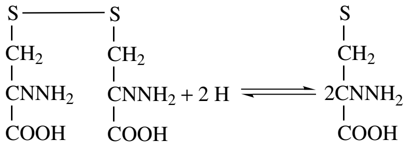
SULFUR (In Biological Systems). Sulfur, in some form, is required by all living organisms. It is utilized in various oxidation states, including sulfide, elemental sulfur, sulfite, sulfate, and thiosulfate by lower forms and in organic combinations by all. The more important sulfur-containing organic compounds include the amino acids (cysteine, cystine, and methionine, which are components of proteins); the vitamins thiamine and

biotin; the cofactors lipoic acid and coenzyme A; certain complex lipids of nerve tissues, the sulfatides; components of mucopolysaccharides, the sulfated polysaccharides; various low-molecular-weight compounds, such as glutathione and the hormones vasopressin and oxytocin; and many therapeutic agents, such as the sulfonamides and penicillins, as well as oral hypoglycemic agents sometimes used in treatment of diabetes mellitus. Sulfhydryl groups of the cysteine residues in enzyme proteins and related compounds, such as hemoglobin, play a key role in many biocatalytic processes; sulfhydryl-disulfide interchange reactions involving the cysteine residues of proteins are critical events in the immune processes, in transport across cell membranes, and in blood clotting. The S—S bridges between these residues are important in the maintenance of the tertiary structure of most proteins.

The electronic structure of sulfur is such that a variety of oxidation states are readily obtainable. It can be said that a sulfur cycle exists in nature, as noted in Fig. 1.

The oxidation and reduction of elemental sulfur and sulfide occur in different species of bacteria, e.g., the oxidation of sulfides via elemental sulfur to sulfate takes place in *Chromatia*, the alternative oxidation to sulfate in *Thiobacillus*. The reduction of sulfate to sulfide occurs in *Desulfovibrio*. The biosynthesis of organic sulfur compounds from sulfate takes place mainly in plants and bacteria, and the oxidation of these compounds to sulfate is characteristic of animal species and of heterotrophic bacteria.

The amino acids cysteine and cystine are interconverted by oxidation-reduction reactions, as shown by



(Cysteine) (Cystine)

Cystine was first isolated from a urinary calculus by Wollaston in 1805. It was shown to be a component of protein by Morner in 1899 and independently by Embden in 1900. Proof of its structure was given by Friedman in 1902. See also **Amino Acids**; **Coenzymes**; **Proteins**; and **Vitamin**.

In the chain from soils to plants to humans, inorganic sulfur, or more accurately, the sulfate ion (SO_4^{2-}), is taken up by plants and converted within the plant to organic compounds (the sulfur amino acids). These amino acids combine with other amino acids to make up plant protein. When the plant is eaten by a human or by livestock animals, the protein is broken down and the amino acids are absorbed from the digestive tract and recombined in the proteins of the animal body. The most important feature of sulfur in the food chain is that plants use inorganic sulfur compounds to make sulfur amino acids, whereas animals and humans use the sulfur amino acids for their own processes and excrete inorganic sulfur compounds resulting from the metabolism of the sulfur amino acids.

Ruminants, such as cattle, sheep, and goats, can use inorganic sulfur in their diets because the microorganisms in the rumen convert the inorganic sulfur into sulfur amino acids and these are then absorbed farther along in the digestive tract.

Soils very low in available sulfur are common in a number of regions of the world. In the United States, low-sulfur soils are frequently found in the Pacific Northwest and in some parts of the Great Lakes states. For many years, sulfur in the form of calcium sulfate was an accessory part of most commercial phosphate fertilizers, and this probably helped to prevent development of widespread sulfur deficiency in crops grown where these fertilizers were used. Volatile sulfur compounds from smoke, particularly before tight pollution controls, were an important source of sulfur for plants growing near industrial centers. In some cases, excessive sulfur in the air can cause injury to the plants. The trend toward high-analysis fertilizers without sulfur and air pollution abatement diminishes some of the inadvertent sources of sulfur for plants and crops and creates a need for more deliberate use of sulfur-containing fertilizers.

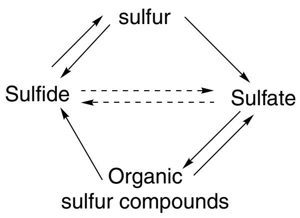


Fig. 1. Sulfur cycle

The extent to which any plant will convert inorganic sulfur taken up from the soil into amino acids and incorporate these into protein is controlled by the genetics of the plant. Increasing the available sulfur in soils to levels in excess of those needed for optimum plant growth will not increase the concentration of sulfur amino acids in plant tissues. To meet the requirements for sulfur amino acids in human diets, the use of food plant species with the inherited ability to build proteins with high levels of sulfur amino acids is required in addition to that supplied by way of the soil.

Since animals tend to concentrate in their own proteins the sulfur amino acids contained in the plants they eat, such animal products (meat, eggs, and cheese) are valuable sources of the essential sulfur amino acids in human diets. In regions where the diet is composed almost entirely of foods of plant origin, deficiencies of sulfur amino acids may be critical in human nutrition. Frequently, persons in such areas (also voluntary vegetarians) are also likely to suffer from a number of other dietary insufficiencies unless supplemental sources are used.

Diets of corn (maize) and soybean meal are usually fortified with sulfur amino acids for pigs and chickens. Sometimes fishmeal, a good source of sulfur amino acids, is added to the diets, or sulfur amino acids synthesized by organic chemical processes may be used.

Since ruminants can utilize a wide variety of sulfur compounds, any practice to increase the sulfur in plants may help to meet the requirements of these animals. Sheep appear to have a higher requirement for sulfur than most other animals, perhaps because wool contains a fairly high level of sulfur. Adding sulfur fertilizers to soils used to produce forage for sheep may improve growth and wool production, even though no increased yield of the forage crop per se may be noted.

Sulfate and Organic Sulfates. Inorganic sulfate ion (SO_4^{2-}) occurs widely in nature. Thus, it is not surprising that this ion can be used in a number of ways in biological systems. These uses can be divided primarily into two categories: (1) formation of sulfate esters and the reduction of sulfate to a form that will serve as a precursor of the amino acids cysteine and methionine; and (2) certain specialized bacteria use sulfate to oxidize carbon compounds and thus reduce sulfate to sulfide, while other specialized bacterial species derive energy from the oxidation of inorganic sulfur compounds to sulfate.

Among the variety of sulfate esters formed by living cells are the sulfate esters of phenolic and steroid compounds excreted by animals, sulfate polysaccharides, and simple esters, such as choline sulfate. The key intermediate in the formation of all of these compounds has been shown to be 3′-phosphoadenosine-5′-phosphosulfate (PAPS). This nucleotide also serves as an intermediate in sulfate reduction.

In organisms that utilize sulfate as a source of sulfur for synthesis of cysteine and methionine, the first step in the reduction process is the formation of PAPS. This is not surprising since the direct reduction of sulfate ion itself is an extremely difficult chemical process. It is known that the reduction of esters and anhydrides occurs much more readily than the reduction of corresponding anions. Following activation, the sulfuryl group of PAPS is reduced to sulfite ion (SO_3^{2-}) by reduced triphosphopyridine nucleotide (TPNH) and a complex enzyme system. Following the reduction of PAPS to sulfite, additional reduction steps readily produce hydrogen sulfide, which appears to be a direct precursor of the amino acid cysteine.

Sulfur Compounds in Onion and Garlic

Dating back to antiquity, there have claims made for the curative and preventative physiological powers of onion and garlic. Dr. Eric Block (State University of New York at Albany), a specialist in the organic chemistry of sulfur, and colleagues, have investigated the chemistry of onion and garlic over a period of years. Some of the results were reported in the Block (1985) reference listed. As pointed out by Block, the cutting of an onion or a garlic bulb releases a number of low-molecular-weight organic molecules that incorporate sulfur atoms in bonding forms rarely encountered in nature. These molecules are highly reactive and they change spontaneously into other organic sulfur compounds, which in turn participate in further transformations. Researchers have cataloged a

number of biological effects of the extracts from these bulbs, including antibacterial and antifungal properties. Other extracts act as antithrombotic agents (inhibit blood platelets). As early as 1721, a drink consisting of wine and macerated garlic (*vinaigre des quatre voleurs*) was used as an antibiotic in France and is still available today! Pasteur (1858) reported on the antibacterial properties of garlic. Albert Schweitzer is reported to have used garlic in the treatment of amoebic dysentery in Africa. As reported by Block, laboratory investigations have shown that garlic juice diluted in one part in 125,000 inhibits the growth of bacteria of the genera *Staphylococcus, Streptococcus, Vibrio* (including *V. cholerae*) and *Bacillus* (including *B. typhosus, B. dysenteriae*, and *B. Enteritidis*). Lacrimatory factors contained in these bulbs are well known.

Serious research commenced in 1844 by Theodor Wertheim, a German chemist. He attributed some of the properties of garlic, "*mainly to the presence of a sulfur-containing, liquid body, the so-called garlic oil. All that is known about the material is limited to some meager facts about the pure product, which is obtained by steam distillation of bulbs of Allium sativum. Since sulfur bonding has been little investigated so far, a study of this material promises to supply useful results for science*." Wertheim suggested the name *allyl* for the oil. Today, allyl is used for chemicals in the C_3H_5 series ($CH_2{=}CHCH_2$).

Another German investigator (Semmler, 1892) also produced garlic oil via steam distillation. The oil yielded diallyl disulfide, $CH_2{=}CHCH_2SSCH_2CH \equiv CH_2$, with minor amounts of diallyl trisulfide and diallyl tetrasulfide present. The oil yielded by similar experimentation with onions was different, containing essentially propionaldehyde, C_2H_5CHO, plus a number of sulfur compounds, of which dipropyl disulfide, $C_6H_{12}S_2$, was one.

Using less harsh methods, Cavallito (1944) produced an oil, $C_6H_{10}S_2O$, by extracting the garlic with ethyl alcohol (room temperature). This oil was found to be more powerful than penicillin or sulfaguanidine against *B. typhosus*. The exact formula of Cavallito's oil was found to be allyl-2-propenethiosulfinate, $CH_2{=}CHCH_2S(O)SCH_2CH{=}CH_2$. Cavallito gave this substance the common name, *allicin*. Precursor molecules for allicin have been identified and it has been established that allicin is not developed in garlic until it is initiated by an enzyme, termed *allinase*.

As pointed out by Block, allinin is the "first natural substance found to display optical isomerism due to mirror-image forms at sulfur as well as at carbon." The research by Block and others is well delineated in the Block (1985) reference. Although much remains to be learned, there is now a long line of hard scientific evidence that garlic and onion have beneficial physiological properties. Most scientists to date suggest that the properties of these bulbs are best exploited by consuming the fresh products, rather than from extracts, particularly when the latter are derived from harsh methodologies, such as steam distillation.

Preservatives. Sulfur compounds, such as sulfur dioxide and sodium bisulfite, are used commercially to preserve the color of various food products, such as orange juice, dehydrated fruits and vegetables, such as apricots, carrots, peaches, pears, potatoes, and many others. Concentrated sulfur dioxide is used in wine-making to destroy certain bacteria. The color preservation of canned green beans and peas is enhanced by dipping the produce in a sulfite solution prior to canning. In 1986, some of these compounds and uses were put under closer regulation in the United States.

The sulfatases are a widely distributed group of enzymes that hydrolyze simple sulfate esters to inorganic sulfate.

Sulfur-Based Pesticides. Sulfur (elemental) has been used as an effective acaricide, fungicide, and insecticide. For ease of use, a number of special formulations are available, ranging from sulfur dusts (up to 95% sulfur); a wettable powder (30 to 90%); and paste-like solutions in which the sulfur is ground to a fine colloidal form. Such formulations may contain up to 50% sulfur. Target plant diseases of sulfur when used as a fungicide include: apple scab, brown rot, downy and powdery mildew, and peach scab. Against insects, sulfur is effective for mite, scale, and thrip. Most formulations are not injurious to honeybees.

Specific sulfur control chemicals include: (1) Calcium polysulfide (lime-sulfur), dating back to the 1850s and available as a solution (up to 31% sulfur) or as a dry powder (up to 70% sulfur). The compound is effective against anthracnose, apple scab, brown rot, powdery mildew, and peach leaf curl—and against mite and scale insects. (2) Sodium polysulfide and sodium thisulfate mixtures—used for spraying and dipping fruit, adding color to the product, and prolonging the period during which the fruit can be picked. (3) Sodium thiosulfate pentahydrate, which prevents discoloration of some green vegetables (use is regulated).

Role of Sulfur in Tidal Wetlands. As pointed out by Luther, et al. (1985 reference listed), the biogeochemical role of sulfur in tidal wetlands presently is subject to considerable research. Sulfur is an important redox element under natural aquatic conditions and is responsible for several important biogeochemical processes, including (1) sulfate reduction, (2) pyrite formation, (3) metal cycling, (4) salt-marsh ecosystem energetics, and (5) atmospheric sulfur emissions. These processes depend upon the formation of one or more sulfur intermediates, which may have any oxidation state between +6 and −2. The intermediate oxidation states may be organic or inorganic. In their study, Luther and colleagues analyzed sulfur species in pore waters of the Great Marsh, Delaware. Anticipated findings reported were bisulfide increases with depth due to sulfate reduction and subsurface sulfate excesses and pH minima, the result of a seasonal redox cycle. Not expected was the pervasive presence of thiols, such as glutathione, particularly during periods of biological production. It appears that salt marshes may be unique among marine systems in producing high concentrations of thiols. Polysulfides, thiosulfate, and tetrathionate also showed seasonal subsurface maxima. The findings suggest a dynamic seasonal cycling of sulfur in salt marshes involving abiological and biological reactions and dissolved and solid sulfur species. The researchers suggest that the chemosynthetic turnover of pyrite to organic sulfur is the likely pathway for this sulfur cycling. It follows that the material, chemical, and energy cycles in wetlands appear to be optimally synergistic.

SULFUROUS ACID. [CAS: 7782-99-2], H_2SO_3, formula weight 82.08, colorless liquid, prepared by dissolving SO_2 in H_2O. Reagent grade H_2SO_3 contains approximately 6% SO_2 in solution. As a bleaching agent, sulfurous acid is used for whitening wool, silk, feathers, sponge, straw, wood, and other natural products. In some areas, its use is permitted for bleaching and preserving dried fruits. The salts of sulfurous acid are sulfites.

Sulfurous acid is a strong reducing agent, being oxidized to H_2SO_4: (1) on standing in contact with air; (2) by chlorine, bromine, iodine, yielding HCl, HBr, or HI, respectively; (3) by HNO_3 or nitrous acid yielding nitric oxide; and (4) by permanganate. Sulfurous acid is itself reduced by zinc and dilute H_2SO_4 to H_2S. Sulfurous acid also may be formed by the reaction of a sulfite or bisulfite solution and an acid.

Sodium sulfite, [CAS: 7757-83-7], Na_3SO_3 and sodium hydrogen sulfite, [CAS: 7631-90-5], $NaHSO_3$ are formed by the reaction of sulfurous acid and NaOH or sodium carbonate in the proper proportions and concentrations. Sodium sulfite, when dry and upon heating, yields sodium sulfate and sodium sulfide. Sodium pyrosulfite (sodium metabisulfite), [CAS: 7681-57-4], $Na_2S_2O_5$ is a common sulfite. Crystalline sulfites are obtained by warming the corresponding bisulfite solutions. Calcium hydrogen sulfite $Ca(HSO_3)_2$ is used in conjunction with excess sulfurous acid in converting wood to paper pulp. Sodium sulfite and silver nitrate solutions react to yield silver sulfite, a white precipitate, which upon boiling decomposes forming silver sulfide, a brown precipitate.

An esterification agent, sulfurous acid forms dimethyl sulfite $(CH_3O)_2SO$, bp 126°C and diethyl sulfite $(C_2H_5O)_2SO$, bp 161°C. Sulfites give a white precipitate with barium chloride, soluble in HCl with evolution of SO_2. Sulfites decolorize iodine in acid solution.

SUPERCONDUCTIVITY. A property of a material that is characterized by zero electric resistivity and, ideally, zero permeability. The phenomenon of superconductivity was discovered in 1911 by Heike Kamerlingh Onnes (University of Leiden) as the outcome of a remarkable achievement in those years—the liquefaction of helium for the first time. Helium condenses at atmospheric pressure at 4.2°K. Onnes, using the newly available very low temperature substance, proceeded to investigate the electrical resistance of various metals at low temperatures. Even prior to quantum mechanics, it had been predicted that if absolute zero could be achieved in a metal having a perfectly regular interatomic structure, the electrical resistance of the metal would be zero. Onnes found that the resistance of a mercury wire suddenly dropped to zero at 4.2°K, which indeed is a very low temperature, but still well above absolute zero. Onnes and other investigators at Leiden researched superconductivity in other metals, such as lead, which was found to become superconductive at 7.2°K. It should be mentioned at this point that scientists of that period were biased in their thinking of conductivity and superconductivity in terms of metals. The first stable conducting organic material was not synthesized until 1960 and it was not until 1979 that a superconducting organic material was isolated. The so-called "hottest" superconductor was announced in mid-1993 by a research team at Eidgenossische Technische Hochschule in Zurich. The new material, considered toxic, is made of two distinct compounds that commence to be superconductive at 133°K. Prior record was claimed for $Tl_2Ca_2Ba_2Cu_3O_{10}$ at 127°K.

Rediscovery. The topic and potential of superconductivity essentially was rediscovered in the late 1970s and early 1980s, during which period the research activity safely can be described as zealous. This was fueled by the scores of probable applications of superconductors, but which to date largely remain as promises. Research continues at a good pace, and the topic is much better understood as compared with a decade ago. As pointed out later in this article, much excellent technological fallout has occurred from many millions of dollars invested in research. The search for the ultimately practical superconductor, although still elusive, has reinforced the multidisciplinary sciences involved, notably physics and chemistry.

Application Targets. Among the ultimately practical applications for superconductivity, especially those of significant future commercial values, are: (1) magnetic shielding, (2) magnetic resonance imaging magnets for medicine and research, (3) electric utility transmission lines and load-leveling storage coils, (4) magnetic separators for materials processing, (5) higher-speed (10×) switching and signal transmission for computers, (6) more compact electronics with finer interconnect lines, (7) extremely compact electric motors and actuators, (8) no-loss portable electrical storage "batteries," and (9) noncontact bearings and magnetically levitated vehicles. Special areas of interest by the military in superconductors include (1) infrared optical detector elements, (2) high-speed millimeter and submillimeter-wave electronics for advanced radar countermeasures, (3) magnetic anomaly detection of submarines, and (4) free-electron laser components.

Considerable research of a contemplative or assumptive nature continues to go forward—that is, studying how the "ideal" superconductor can be applied, once developed. Examples of progress are shown in Figs. 1, 2, and 3.

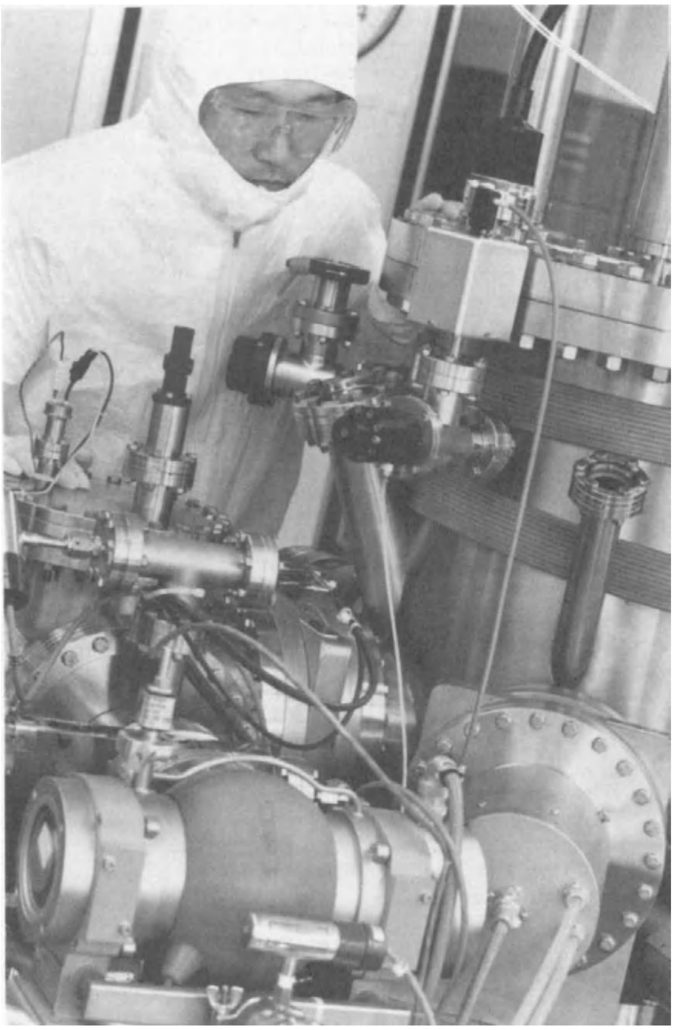

Fig. 1. Special equipment required to fabricate low-temperature superconducting junctions. Josephson junctions are comprised of aluminum oxide sandwiched between layers of niobium. These trilayer devices are considered vital to the very-high-speed signal processing demands of next-generation computers, radar, and communication systems. Shown in illustration is scientist Dr. Joonhee Kang. (Westinghouse Electric Corporation)

Fundamental Research Findings

For several years following the previously mentioned work of the Louden scholars, investigators concentrated principally on metallic elements and alloys, including indium, tin, vanadium, molybdenum, niobium-zirconium, and niobium-tin, among many others. A number of basic discoveries were made. For example, finding that the property of superconductivity could be destroyed by the application of a magnetic field equal to or greater than a critical field H_c. This H_c, for a given superconductor, is a function of the temperature given approximately by

$$H_c = H_0(1 - T^2/T_c^2) \quad (1)$$

where H_0, the critical field at 0°K, is in general different for different superconductors and has values from a few gauss to a couple of thousand gauss. For applied magnetic fields less than H_c, the flux is excluded from the bulk of the superconducting sample, penetrating only to a small depth λ into the surface. The value of λ (called the penetration depth) is in the range 10^{-5} to 10^{-6} centimeter. Thus the magnetization curve for a superconductor is

$$\begin{aligned} B(\text{inside}) &= 0 && \text{for } H < H_c \\ B(\text{inside}) &= B(\text{outside}) && \text{for } H > H_c \end{aligned}$$

This magnetization behavior is reversible and cannot therefore be explained entirely on the basis of the zero resistance. The reversible magnetization behavior is called the Meissner effect.

The existence of the penetration depth λ suggests that a sample having at least one dimension less than λ should have unusual superconducting properties, and such is indeed the case. Thin superconducting films, of thickness d less than λ, have critical fields higher than the bulk critical field, approximately in the ratio of λ to d. This result follows qualitatively from the thermodynamics of the Meissner effect: the metal in the superconducting state has a lower free energy than in the normal state, and the transition to the normal state occurs when the energy needed to keep the flux out becomes equal to this free energy difference. But in the case of a thin film with $d < \lambda$, there is partial penetration of the flux into the film, and thus one must go to a higher applied field before the free energy difference is compensated by the magnetic energy.

Fig. 2. Electrical lead comprised of a high-temperature superconductor can carry a current of 2000 amperes. A variety of uses include magnetic resonance imaging and superconducting magnetic energy storage. (*Westinghouse Electric Corporation*)

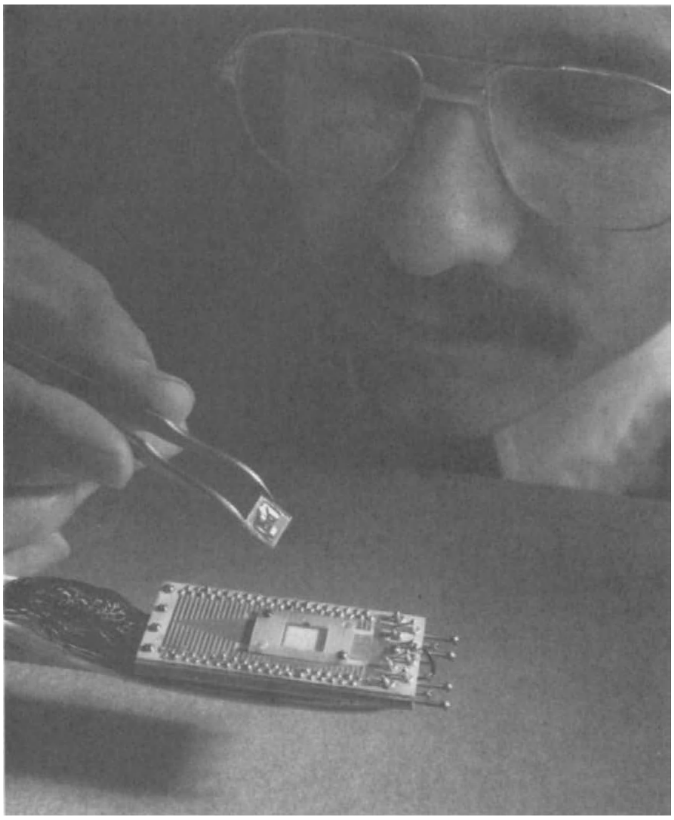

Fig. 3. Scientist Donald L. Miller holds an integrated circuit chip comprising a high-resolution superconducting analog-to-digital converter. The one-square-cen timeter chip, known as a counting converter, holds promise as an unprecedented combination of high resolution and low power consumption, as needed in future air traffic control radar and infrared space-tracking applications. The 12-bit circuit (Josephson junction) has a resolution of 1 part in 4000. (*Westinghouse Electric Corporation*)

It is clear that the existence of the critical field also implies the existence of a critical transport electrical current in a superconducting wire, i.e., that current I_c, which produces the critical field H_c at the surface of the wire. For example, in a cylindrical wire of radius r, $I_c = \frac{1}{2} r H_c$. This result is called the Silsbee rule.

All of the above properties distinguish superconductors from "normal" metals. There is another very important distinction, which contains a clue to understanding some of the properties of superconductors. In a normal metal at 0°K, the electrons, which obey Fermi statistics, occupy all available states of energy below a certain maximum energy called the Fermi energy ζ. Raising the temperature of the metal causes electrons to be singly excited to states just above the Fermi energy. There is for all practical purposes a continuum of such excited energy states available above the Fermi energy. The situation is quite different in a superconductor; it turns out that in a superconductor, the lowest excited state for an electron is separated by an energy gap $\in$ from the ground state. The existence of this gap in the excitation spectrum has been confirmed by a wide range of measurements: electronic heat capacity, thermal conductivity, ultrasonic attenuation, far infrared and microwave absorption, and tunneling. The energy gap is a monotonically decreasing function of temperature, having a value ~3.5 kT_c at 0°K (where k is the Boltzmann constant) and vanishing at T_c.

The superconducting state has a lower entropy than the normal state, and therefore one concludes that superconducting electrons are in a more ordered state. Without, for the present, inquiring more deeply into the nature of this ordering, one can state that a spatial change in this order produced say by a magnetic field will occur, not discontinuously, but over a finite distance ζ, which is called the *coherence length*. The coherence length represents the range of order in the superconducting state and is typically about 10^{-4} centimeter, though we shall see later that it can in some superconductors take much lower values and lead to some remarkable properties.

Measurements of the transition temperature on different isotopes of the same superconductor showed that T_c is proportional to $M^{-1/2}$, where M is the isotopic mass. This isotope effect suggests that the mechanism underlying superconductivity must involve the properties of the lattice, in addition to those of the electrons. Another indication of this is given by the behavior of allotropic modifications of the same element: white tin is superconducting, while grey tin is not, and the hexagonal and face-centered cubic phases of lanthanum have different transition temperatures. A third, and most striking, indication is that the current vs voltage characteristic of a superconducting tunneling junction shows a structure which is intimately related to the phonon spectrum of the superconductor.

The superconducting properties of alloys present a bewildering variety of phenomena. They show a great deal of magnetic hysteresis, with little indication of a perfect Meissner effect. The Silsbee rule is inapplicable, and the resistive transition occurs at fields generally very much higher than in pure superconductors. For example, a wire of Nb_3Sn can carry a current of 10^5 amperes/cubic centimeter in an applied field of 100 kilogauss, while a similar wire of lead would carry about 10^3 amperes/cubic centimeter in a field of only 100 gauss. When experiments are done using well-annealed (preferably single-crystal) alloys, it is found that the critical currents drop considerably, and the magnetic behavior becomes reversible but still quite unlike that of pure superconductors. The flux is excluded from the interior of the sample up to a well-defined field H_{c1}. When the applied field is raised further, flux begins to penetrate, even though the resistance remains zero, until a second critical field H_{c2} is reached, at which the flux penetration is complete, and normal resistance is abruptly restored.

Superconductivity Theory

The theory of superconductivity has developed along two lines, the phenomenological and the microscopic. The phenomenological treatment was initiated by F. London, who modified the Maxwell electromagnetic equations so as to allow for the Meissner effect. His theory explained the existence and order of magnitude of the penetration depth, and gave a qualitative account of some of the electrodynamic properties. The treatment was extended by V.L. Ginzburg and L.D. Landau, and by A.B. Pippard, who in particular emphasized the concept of the range of coherence. A.A.

Abrikosov used these ideas to develop a model for alloy superconductors. He showed that if the electronic structure of the superconductor were such that the coherence length ζ becomes smaller than the penetration depth λ, one would get magnetic behavior similar to that observed in alloys, with two critical fields H_{c1} and H_{c2}. The problem of high critical currents in unannealed (or otherwise metallurgically imperfect) alloys and compounds is more complicated because it involves the interaction between the microscopic metallurgical structure and the superconducting properties. This is an area of great research activity because of the technological implication to be mentioned later.

The microscopic theory of superconductivity was initiated by H. Fröh lich, who first recognized the importance of the interactions of electrons with lattice vibrations and in fact predicted the isotope effect before its experimental observation. The detailed microscopic theory was developed by J. Bardeen, L.N. Cooper and J.R. Schrieffer in 1957, and represents one of the outstanding landmarks in the modern theory of solids. The BCS theory, as it is called, considers a system of electrons interacting with the phonons, which are the quantized vibrations of the lattice. There is a screened coulomb repulsion between pairs of electrons, but in addition there is also an attraction between them via the electron-phonon interaction. If the net effect of these two interactions is attractive, then the lowest energy state of the electron system has a strong correlation between pairs of electrons with equal and opposite momenta and opposite spin and having energies within the range $k\theta$ (where θ is the Debye temperature) about the Fermi energy. This correlation causes a lowering of the energy of each of these Cooper pairs (named after L.N. Cooper who first pointed out their existence on the basis of some general arguments) by an amount $\in$ relative to the Fermi energy. The energy $\in$ may be regarded as the binding energy of the pair, and is therefore the minimum energy which must be supplied in order to raise an electron to an excited state. We see thus that the experimentally observed energy gap follows from the theory. The magnitude ε_0 of the gap at 0°K is

$$\varepsilon_0 \approx 4k\theta \exp\left(-\frac{1}{NV}\right)$$

where N is the density of electronic states at the Fermi energy and V is the net electron-electron interaction energy. The superconducting transition temperature T_c is given by

$$3.5kT_c \approx \varepsilon_0$$

It has been shown that the BCS theory does lead to the phenomenological equations of London, Pippard and Ginzburg and Landau, and one may therefore state that the basic phenomena of superconductivity are now understood from a microscopic point of view, i.e., in terms of the atomic and electronic structure of solids. It is true, however, that we cannot yet, *ab initio*, calculate V for a given metal and therefore predict whether it will be superconducting or not. The difficulty here is our ignorance of the exact wave functions to be used in describing the electrons and phonons in a specific metal, and their interactions. However, we believe that the problem is soluble in principle at least.

The range of coherence follows naturally from the BCS theory, and we see now why it becomes short in alloys. The electron mean free path is much shorter in an alloy than in a pure metal, and electron scattering tends to break up the correlated pairs, so that for very short mean free paths one would expect the coherence length to become comparable to the mean free path. Then the ratio $\kappa \approx \lambda/\zeta$ (called the Ginzburg-Landau order parameter) becomes greater than unity, and the observed magnetic properties of alloy superconductors can be derived. The two kinds of superconductors, namely those with $k < 1/\sqrt{(2)}$ and those with $k > 1/\sqrt{(2)}$ (the inequalities follow from the detailed theory) are called respectively type I and type II superconductors.

Challenges to Established Theories. It is interesting to note that some theoreticians struggle with describing how superconductivity occurs at high temperatures in the newer, ceramic superconductors. This is understandable because the classic theory of superconductivity is tied to metals. Most ceramic superconductors discovered to date incorporate distinctive layers of copper and oxygen atoms. One question posed by some researchers, "Is the mechanism of high-temperature superconductivity the same in hole superconductors as it is in electron superconductors?"

Researchers at the Brookhaven National Laboratory, in applying X-ray techniques to a cerium-doped electron superconductor developed at the University of Tokyo, found that the holes of a hole superconductor are linked to oxygen atoms in the copper-oxygen layers, whereas in an electron superconductor the electrons are associated with copper atoms. This is exemplary of how easy it is for former theories to become outdated when new material combinations are tested for their superconductivity.

Superconductivity Research

In 1962, B. Josephson recognized the implications of the complex order parameter for the dynamics of the superconductor, and in particular when one considers a system consisting of two bulk conductors connected by a "weak link." This research led to the development of a series of weak link devices commonly called Josephson junctions. See also **Josephson Tunnel-Junction**. These devices hold much promise for achieving ultra high-speed computers where switching time is of the order of 10^{-11} second.

Good success also has been achieved in the use of certain type II superconductors, such as Nb-Zr and Nb-Ti alloys, and Nb_3Sn, in making electromagnets. In a conventional electromagnet employing normal conductors, the entire electric power applied to the magnet is consumed as Joule heating. For a magnet to produce 100 kilogauss in a reasonable volume, the power requirement can run into megawatts. In striking contrast, a superconducting magnet develops no Joule heat because its resistance is zero. Indeed, if such a magnet has a superconducting shunt placed across it after it is energized, the external power supply can be removed, and the current continues to flow indefinitely through the magnet and shunt, maintaining the field constant. Superconducting magnets have been constructed producing very strong fields in usable volumes. There is a natural upper limit to the critical field possible in such superconductors, given by the paramagnetic energy of the electrons (due to their spin moment) in the normal state becoming equal to the condensation energy of the Cooper pairs in the superconducting state. This leads to a limit of about 360 kilogauss for a superconductor with a T_c of 20°K.

As investigators accumulated data upon data, many emphasized the practical as well as theoretical aspects of superconductors. The ultimate superconductor, of course, would be one that operated at room temperature or above. The materials must be manufacturable in a useful form, such as strong ductile wires for high-field magnets, electrical machinery, and power transmission lines, situations which could be even more important in commercial and industrial application than their value to science per se. (Traditionally, superconducting materials have been hard, brittle, and difficult to process.) Although superconductors that would operate at room temperature and above present a long-range target, lesser targets, including practical ways to cool them with liquid nitrogen instead of liquid helium and possibly, even better, operate them within a closed-cycle refrigeration system is the goal in the shortrange. Useful superconductors in large-scale applications must retain their properties not only at high temperatures, but also in the presence of high magnetic fields and while carrying large electrical currents. Praveen Chaudhari (IBM) has observed that new superconductors will enter the marketplace rapidly when intensive materials engineering produces easily cooled, mechanically robust conductor configurations that can handle high current densities (100, 000 + A/cm^2) under powerful magnetic fields (10 + T), while maintaining stable superconductivity.

Johannes Georg Bednorz and Karl Alexander Mueller (IBM Zurich Research Laboratory) after several years devoted to a study of oxide compounds (not in terms of superconductivity) proceeded with the working hypothesis that an increase in the density of charge carriers in a material (either as electrons or as positively charged "holes") possibly would lead to a rise in transition temperature. They commenced a search for nickel- and copper-containing oxides. Early in 1986, they found a certain form of barium lanthanum copper oxide that evidenced the onset of superconductivity at temperatures as high as 35°K (12 degrees over the previous record). They encountered skepticism, because the facts did not square with accepted theory that limits the phenomenon to well below 35°K. Shortly thereafter, however, researchers at the University of Tokyo, the University of Houston, and AT&T Bell Laboratories confirmed the Bednorz-Mueller findings. On October 14, 1987, the Nobel prize in physics was awarded to these two researchers and a speaker for the Royal Swedish Academy of Sciences observed that their work inspired "the explosive development in which hundreds of laboratories the world over commenced work on similar material." [It should be observed that Ching-Wu Chu and colleagues (University of Houston) did announce in February 1987 that a related class of ceramics (a certain form of yttrium barium copper oxide) remained superconducting up to 94°K, proclaiming that to be the

first superconductor which could be cooled by liquid nitrogen (bp = 77°K) instead of requiring helium.] That announcement in itself also precipitated a "rush" of researchers to the ceramics.

Technological Fallout of Superconductivity Research

While in the course of finding viable superconductors for commercial applications, researchers have produced valuable ancillary information.

Quantization of Energy. In a scholarly paper, D.G. McDonald (U.S. National Institute of Standards and Technology, Boulder, Colorado) observes, "Ideas about quantized energy levels originated in atomic physics, but research in superconductivity has led to unparalleled precision in the measurement of energy levels. Microscopic things can be identical; macroscopic things cannot. This proposition is so imbued in the minds of physicists that it is interesting to see that it is false in the following sense. In the past, physicists believed that only atoms and molecules could have identical states of energy, but recent experiments have shown that much larger bodies, superconductors in macroscopic quantum states, have equally well-defined energies." In the paper, McDonald uses the novelty of the Josephson effect to illustrate the primary point of the technical paper. See McDonald reference listed.

Structural Chemistry. In an enlightening paper, R.J. Cava (AT&T Bell Laboratories) asserts, "The discovery of high-temperature superconductivity in oxides based on copper and rare and alkaline earths at first caught the solid-state physics and materials science communities completely by surprise. Since the earliest 30 to 40°K superconductors based on $La_{2-x}(Ca,Sr,Ba)_xCuO_4$, many new superconducting copper oxides have been discovered, with ever-increasing chemical and structural complexity. The current record transition temperature is held[1] by $T1^2Ba^2Ca^2Cu^3O^{10}$, a material whose processing requires the stoichiometric control of five elements, each with considerably different chemical characteristics." In the Cava paper, the crystal structures of the known copper oxide superconductors are described, with particular emphasis on the manner in which they fall into structural families. The local charge picture—a framework for understanding the influence of chemical composition, stoichiometry, and doping on the electrical properties of complex structures—is also described.

This probing of complex and previously unattended solid materials typifies technical fallout from superconductor research.

Impact on Materials Processing and Chemical Engineering. In an interesting paper, R. Kumar (Indian Institute of Science, Bangalore) points out how processing considerations for achieving high-temperature superconductors has introduced new process engineering problems not contemplated heretofore. In a paper (reference listed), Kumar observes that processes involve multicomponent solid-solid reactions; mixing of fine powders; simultaneous precipitation of many ions from solutions, emulsions, microemulsions, and liquid membranes; the flow of cohesive powders with and without binders; the flow of thin films over partially wetted particles; grain boundary growth and composition; quick evaporation using pulsed lasers; mixing of molecules during their flight paths and the influence of oxygen jets; deposition of particles on substrates; and other relatively unfamiliar processing techniques.

SUPERCOOLING. The cooling of a liquid below its freezing point without the separation of the solid phase. This is a condition of metastable equilibrium, as is shown by solidification of the supercooled liquid upon the addition of the solid phase, or the application of certain stresses, or simply upon prolonged standing.

SUPERFLUIDITY. The term used to describe a property of condensed matter in which a resistance-less flow of current occurs. The mass-four isotope of helium in the liquid state, plus over 20 metallic elements, are known to exhibit this phenomenon. In the case of liquid helium, these currents are hydrodynamic. For the metallic elements, they consist of electron streams. The effect occurs only at very low temperatures in the vicinity of the absolute zero (−273.16°C or 0 K). In the case of helium, the maximum temperature at which the effect occurs is about 2.2 K. For metals, the highest temperature is in the vicinity of 20 K.

If one of the metals (commonly referred to as superconductors) is cast in the form of a ring and an external magnetic field is applied perpendicularly to its plane and then removed, a current will flow round the ring induced by Faraday induction. This current will produce a magnetic field, proportional to the current, and the size of the current may be observed by measuring this field. Were the ring (e.g., one made of lead) at a temperature above 7.2 K, this current and field would decay to zero in a fraction of a second.

But with the metal at a temperature below 7.2 K before the external field is removed, this current shows no sign of decay even when observations extend over a period of a year. As a result of such measurements, it has been estimated that it would require 10^{99} years for the supercurrent to decay. Such persistent or "frictionless" currents in superconductors were observed in the early 1900s—hence they are not a recent discovery.

In the case of liquid helium, these currents are hydrodynamic, i.e., they consist of streams of neutral (uncharged) helium atoms flowing in rings. Since, unlike electrons, the helium atoms carry no charge, there is no resulting magnetic field. This makes such currents much more difficult to create and detect. Nevertheless, as a result of research carried out in England and the United States during the late 1950s and early 1960s, the existence of supercurrents in liquid helium has been established.

SUPERMOLECULAR CHEMISTRY. See **Molecular Recognition**.

SUPEROXIDES. These compounds are characterized by the presence in their structure of the O_2^- ion. The O_2^- ion has an odd number of electrons (13) and, as a result, all superoxide compounds are paramagnetic. At room temperature all superoxides have a yellowish color. At low temperature many of them undergo reversible phase transitions which are accompanied by a color change to white. Superoxide compounds known to be stable at room temperature are:

Sodium superoxide	NaO_2
Potassium superoxide	KO_2
Rubidium superoxide	RbO_2
Cesium superoxide	CsO_2
Calcium superoxide	$Ca(O_2)_2$
Strontium superoxide	$Sr(O_2)_2$
Barium superoxide	$Ba(O_2)_2$
Tetramethylammonium superoxide	$(CH_3)_4NO_2$

The superoxides are generally prepared by one of three methods:

(1) Direct oxidation of the metal, metal oxide, or metal peroxide with pure oxygen or air. All alkali metal superoxides, with the exception of lithium have been prepared in this manner. The superoxides of potassium, rubidium, and cesium form quite readily upon direct oxidation of the molten metal in air or oxygen at atmospheric pressure. Attempts to prepare sodium superoxide under the same conditions result in the formation of sodium peroxide, Na_2O_2. As a result, it was generally felt, prior to 1949, that sodium superoxide was not stable enough to be synthesized. However, in 1949 this superoxide was prepared for the first time, in good yield and purity, by the direct oxidation of sodium peroxide at 490°C under an oxygen pressure of 298 atm. Sodium superoxide is now commercially available and is prepared by a high-temperature, high-pressure, direct oxidation of the peroxide. It is now known that the pale yellow color common in commercial grade sodium peroxide is due to the presence of 5 to 10% sodium superoxide.

(2) Oxidation of an alkali metal dissolved in liquid ammonia with oxygen. All the alkali metal superoxides have been prepared by this method. Although lithium superoxide (LiO_2) has not been isolated in a room temperature-stable form, it has been demonstrated that when lithium is oxidized in liquid ammonia at −78°C the superoxide does form and is stable at that temperature.

(3) Reaction of hydrogen peroxide with strong bases. Hydrogen peroxide can be caused to react with strong inorganic bases to form intermediate peroxide compounds which disproportionate to yield superoxides. The alkaline earth metal superoxides, and sodium, potassium, rubidium, cesium, and tetramethylammonium superoxide have been obtained via this process. Claims have also been made for the synthesis of lithium superoxide via this method; however, such claims have not been adequately substantiated.

Using the formation of potassium superoxide as an example, the reactions involved in this process are:

$$2KOH + 3H_2O_2 \longrightarrow K_2O_2 \cdot 2H_2O_2 + 2H_2O$$

followed by

$$K_2O_2 \cdot 2H_2O_2 \longrightarrow 2KO_2 + 2H_2O.$$

From the commercial point of view the most important of the superoxides is KO_2. This compound has been in large scale commercial production for many years. It is manufactured in very good yield and purity by air oxidation of the molten metal. This compound is utilized in self-contained breathing devices which are widely used in fire fighting operations and in mine rescue work. The function of the superoxide is to provide oxygen and to remove exhaled carbon dioxide. This unique capability of superoxides is explained by the following chemical reactions:

$$2KO_2(s) + HOH(v,l) \longrightarrow 2KOH(s,soln) + 3/2O_2(g)$$

and

$$2KOH(s,soln) + CO_2(g) \longrightarrow K_2CO_3(s,soln) + H_2O$$

where s = solid, v = vapor, l = liquid, g = gas, and soln = solution.

Up to 34% of the weight of potassium superoxide is available as breathing oxygen. The lower molecular weight NaO_2 is capable of supplying up to 43% of its weight as oxygen. Thus, sodium superoxide is a better oxygen storage compound. However, it has not been widely used due to its relatively high cost. The cost of KO_2 is much less. The use of superoxides for maintaining proper oxygen and carbon dioxide levels in the atmospheres of space vehicles, space stations, and submarines has been of some interest.

The handling and storage of superoxides requires care and caution. Chemically they are powerful oxidizing agents and strong bases and as a result, they react vigorously with acids and organic materials. All superoxides are extremely hydroscopic, thus their safe storage requires the use of tightly sealed, clean, dry containers.

The chemical bond between the superoxide ion, O_2^-, and the metal ion is ionic in nature. Melting points of potassium, rubidium and cesium superoxide have been determined, and in keeping with the ionic nature of the compounds, the melting temperatures are high, in the order of 400°C.

The most reliable technique for the analysis of superoxides is that developed by Seyb and Kleinberg. In this method the superoxide sample is treated with a mixture of glacial acetic acid and diethyl or dibutyl phthalate. The superoxide reacts with the acetic acid to yield oxygen, hydrogen peroxide, and potassium acetate. The amount of superoxide in the sample is related to the amount of oxygen evolved which is measured with a gas buret. The stoichiometry of the analytical reaction is:

$$2KO_2 + 2HC_2H_3O_2 \longrightarrow 2KC_2H_3O_2 + H_2O_2 + O_2$$

It is important that a sufficiently dilute glacial acetic acid-diethyl phthalate mixture be used. Contact of undiluted glacial acetic acid with the superoxide will result in a violent and uncontrollable reaction.

As a result of the paramagnetic nature of superoxides, it is possible to determine their purity by means of paramagnetic susceptibility measurements. The use of this method is limited by its poor accuracy.

Westerley, Rhode Island

SUPER POSITION (Nernst Principle of). The potential difference between junctions in similar pairs of solutions which have the same ratio of concentrations are the same even if the absolute concentrations are different, e.g., the same potential difference exists between normal solutions of HCl and KCl as exists between tenth-normal solutions of HCl and KCl.

SUPERSATURATED VAPOR. A vapor that remains dry, although its heat content is less than that of dry and saturated vapor at the pressure. Supersaturation is an unstable condition, and is found in the steam emerging from the nozzles of a steam turbine. The abnormality of the phenomenon is similar to that of supercooling. See also **Supercooling**. Supersaturation of the steam probably results from the very rapid expansion of steam in the nozzle, permitting the traverse of a short distance before the condensation of moisture is completed. At a certain definite point, however, known as the Williams limit, the supersaturation vanishes, and the steam regains the wet state which would be normal in view of the pressure and the heat content. Supersaturation of vapor is impossible in the presence of numerous charged ions or dust particles.

SUPERSATURATION (Chemical). The condition existing in a solution when it contains more solute than is needed to cause saturation. Thermodynamically, this type of supersaturation is closely allied to supersaturation of a vapor, since the solute cannot crystallize out in solutions free from impurities or seed crystals of the solute. See also **Supersaturated Vapor**.

SURFACE. In physical chemistry the area of contact between two different phases or states of matter, e.g., finely divided solid particles and air or other gas (solid-gas); liquids and air (liquid-gas); insoluble particles and liquid (solid-liquid). Surfaces are the sites of the physiochemical activity between the phases that is responsible for such phenomena as adsorption, reactivity, and catalysis. The depth of a surface is of molecular order of magnitude. The term *interface* is approximately synonymous with *surface*, but it also includes dispersions involving only one phase of matter, i.e., solid-solid or liquid-liquid.

SURFACE ACTIVE AGENTS. See **Detergents**.

SURFACE CHEMISTRY. This topic deals with the behavior of matter, where such behavior is determined largely by forces acting at surfaces. Since only condensed phases, i.e., liquids and solids, have surfaces, studies in surface chemistry require that at least one condensed phase be present in the system under consideration. The condensed phase may be of any size ranging from colloidal dimensions to a mass as large as an ocean. Interactions between solids, immiscible liquids, liquids and solids, gases and liquids, gases and solids, and different gases on a surface fall within the province of surface chemistry.

Surface forces determine whether one material will wet and spread on a substrate, e.g., whether a liquid will wet a solid and spread into crevices and pores to displace air. This seemingly simple phenomenon is of cardinal importance in determining the strength of adhesive joints and of reinforced plastics; it establishes the printing and writing qualities of inks; lubricants will wet and spread over entire surfaces or be confined to limited working areas depending upon built-in wetting or nonwetting properties; ores are floated if the surrounding liquid is readily displaced by air bubbles; the dispersion of pigments in paints depends upon wetting of the individual particles by the liquid; the action of a foam breaker frequently depends upon its ability to spread on the foam; secondary oil recovery often involves displacement of oil from sand by water; wetting is also a factor in detergency; water and soil repellancy depend upon nonwetting.

Wetting or nonwetting often depends upon the adsorption of a solute at a surface or interface. The bulk liquid phase either advances or recedes, depending upon the nature of the solute and the condensed phase. However, there are many phenomena where adsorption is essential to the process but wetting is not a factor. For example, toxic gases and cigarette tars are removed by adsorption on suitable substrates; color bodies are removed from vegetable oils by adsorption on activated clays; heterogeneous catalysis requires the adsorption of reactants on the catalytic surface; dyeing of fabrics is an adsorption process; dispersions and emulsions are stabilized by the adsorption of suitable solutes and flocculated by the adsorption of other solutes; foaming depends upon adsorption; chromatography is a preferential adsorption process; the action of many corrosion inhibitors depends upon their adsorption on metal surfaces.

The spreading of an insoluble monolayer is a process analogous to adsorption with a number of specialized applications. Thus, cetyl alcohol is spread as a monoloayer on reservoirs to retard the evaporation of water. Some antifoaming agents act by spreading as monolayers.

Because of the widespread applications of surface chemistry, practically all industries, knowingly or otherwise, make use of the principles of surface chemistry. Countless cosmetic and pharmaceutical products are emulsions—lotions, creams, ointments, suppositories, etc. Food emulsions include milk, margarine, salad dressings and sauces. Adhesive emulsions, emulsion paints, self-polishing waxes, waterless hand cleaners and emulsifiable insecticide concentrates are commonplace examples of emulsions, which fall within the province of surface chemistry. Other products which function in accordance with the principles of surface chemistry include detergents of every variety, fabric softeners, antistatic agents, mold releases, dispersants and flocculants.

Surface forces are merely an extension of the forces acting within the body of a material. A molecule in the center of a liquid drop is attracted equally from all sides, while at the surface the attractive forces acting between adjacent molecules results in a net attraction into the bulk phase in a direction normal to the surface. Because of unbalanced attraction at the surface, the tendency is for these molecules to be pulled from the surface into the interior, and for the surface to shrink to the smallest area that can enclose the liquid. The work required to expand a surface by 1 sq cm in opposition to these attractive forces is called the surface tension.

This concept applies equally well to solids. Molecules in a solid surface are also in an unbalanced attractive field and possess a surface tension or surface free energy. While the surface tension of a liquid is easily measured, this is much more difficult to do for a solid, since to increase the surface extraneous work must be done to deform the solid.

In the case of solid or liquid solutions it is frequently observed that one component of the solution is present at a greater concentration in the surface region than in the bulk of the solution. Thus, for an ethanol-water system, the surface region will contain an excess of ethanol. The concentration of water will be higher at the surface than in the bulk, if the solute is sulfuric acid. Molybdenum oxide dissolved in glass will concentrate at the surface of the glass. The concentrating of solute molecules at a surface is called adsorption.

If a clean solid is exposed to the atmosphere, molecules of one or more species present in the atmosphere will deposit on the surface. If the clean solid is immersed in a solution, molecules of one or another species present in the solution will be apt to concentrate at the solid-liquid interface. These phenomena are also referred to as *adsorption*.

All adsorption processes result from the attraction between like and unlike molecules. For the ethanol-water example given above, the attraction between water molecules is greater than between molecules of water and ethanol. As a consequence, there is a tendency for the ethanol molecules to be expelled from the bulk of the solution and to concentrate at the surface. This tendency increases with the hydrocarbon chain-length of the alcohol. Gas molecules adsorb on a solid surface because of the attraction between unlike molecules. The attraction between like and unlike molecules arises from a variety of intermolecular forces. London dispersion forces exist in all types of matter and always act as an attractive force between adjacent atoms and molecules, no matter how dissimilar they are. Many other attractive forces depend upon the specific chemical nature of the neighboring molecules. These include dipole interactions, the hydrogen bond and the metallic bond.

There is an additional explanation for the tendency of a solute such as ethanol to concentrate at the surface of a liquid, which originates with Langmuir. According to his "principle of independent surface action" each portion of a molecule behaves independently of other portions of the molecule in its attraction to other molecules or functional groups on a molecule. The attraction between the CH_3CH_2 portion of the ethanol molecule and water arises from relatively weak London dispersion forces, as compared with the additional attraction of strong hydrogen-bonding forces acting between the hydroxyl group of the alcohol and water. Hydrogen bonding is also responsible for the strong attraction between water molecules. As a consequence, not only is the alcohol concentrated at the surface, it is also oriented with the hydroxyl group toward the water and the hydrocarbon chain directed outward. Since the attraction between adjacent hydrocarbon molecules is less than that between adjacent water molecules, hydrocarbon liquids have lower surface tensions than water, and the surface tension of an aqueous alcohol solution is intermediate between that of liquid hydrocarbons and water.

As noted earlier, the phenomenon of adsorption is encountered in diverse applications. Medical applications are often the most complex and the least understood. For example, replacement hearts and kidney machines require plastics that can be kept in contact with human blood for long periods of time. However, foreign material in contact with blood results in clotting. The material first becomes coated with adsorbed protein. Some time later the clotting process begins, apparently due to activation of the Hageman factor, one of the proteins in blood, at the blood-material interface. The activation initiates a chain reaction that results in the conversion of fibrinogen to fibrin. It has been suggested that the Hageman factor is helical in form and that adsorption results in an unfolding of the protein helix with exposure of certain active sites which then initiate the clotting of blood. Other proteins are also adsorbed and their biological function may be altered, but little is known about this.

The ideal surface for contact with human blood is the surface of blood vessels, and the immediate surface contains heparinoid complexes. Heparin, a negatively charged polysaccharide, has been bonded to silicon rubber and other polymers. In one procedure, a quaternary ammonium compound is first adsorbed on the polymer substrate and heparin is in turn adsorbed on the positively charged surface. Chemical bonding of heparin has also been achieved. Such surfaces do not cause clotting of contacted blood.

As noted earlier, the phenomenon of adsorption is encountered in such diverse applications as the separation of components in chromatography, the removal of toxic gases by activated charcoal, heterogeneous catalytic reactions and the dyeing of fabrics. The surface area of solids is most

commonly determined by the adsorption of nitrogen on the surface of the solid at −915°C. Nitrogen is assigned an area of 16.2 Å^2 per molecule. The method is due to Brunauer, Emmett and Teller and is referred to as the BET method for determining surface area.

The fundamental adsorption equation is due to Gibbs. In the case of a solution containing a single solute,

$$\Gamma = \frac{1}{RT}\left(\frac{\partial \dot{\gamma}}{\partial \ \ln \ a}\right)_T$$

where Γ is the excess of solute at the surface as compared with the concentration of solute in the bulk liquid expressed in moles per sq cm, R is the gas constant, T is the absolute temperature γ is the surface tension of the solution, and a is the activity of the solute. Where the solution is sufficiently dilute, the concentration of the solute may be substituted for its activity.

The equation also applies to the adsorption of a gas on a solid. At low gas pressures, p, the equilibrium pressure of the gas can be substituted for a, the activity of the solute. The amount of gas adsorbed ν/V is equivalent to the surface excess Γ, where ν is equal to the volume of gas adsorbed per gram of solid and V is the molar volume of the gas. The total free energy change at constant pressure is $\Sigma\delta\gamma$, where Σ is the area per gram of solid.

When a drop of liquid is placed on the surface of a solid, it may spread to cover the entire surface, or it may remain as a stable drop on the solid. There is a solid-liquid interface between the two phases. In the case of liquids that do not spread on the solid, the bare surface of the solid adsorbs the vapor of the liquid until the fugacity of the adsorbed material is equal to that of the vapor and the liquid.

The equation relating contact angle to surface tension, generally ascribed to Young or Dupre, is

$$\gamma_{\mathrm{Se}} = \gamma_{\mathrm{SL}} + \gamma_{\mathrm{L}} \cos\ \theta$$

where γ_{Se} is the surface tension of the solid covered with adsorbed vapor, γ_{SL} is the solid-liquid interfacial tension, γ_{L} is the surface tension of the liquid and θ is the contact angle.

As a general rule, organic liquids and aqueous solutions will spread on high-energy surfaces, such as the clean surfaces of metals and oxides. The rule has a number of exceptions. For one, certain organic liquids will deposit a low-energy film by adsorption on higher-energy surfaces over which the bulk liquid will not spread.

Zisman discovered that there is a critical surface tension characteristic of low-energy solids, such as plastics and waxes. Liquids that have a lower surface tension than the solid will spread on that solid, while liquids with a higher surface tension will not spread. Examples of critical surface tension values for plastic solids in dynes per cm are: “Teflon,” 18; polyethylene, 31; polyethylene terephthalate, 43; and nylon, 42–46. As one indication of the way this information can be used in practical applications, one can consider the bonding of nylon to polyethylene. If nylon were applied as a melt to polyethylene, it would not wet the lower-energy polyethylene surface and adhesion would be poor. However, molten polyethylene would spread readily over solid nylon to provide a strong bond.

There are a large number of materials that exhibit a pronounced tendency to concentrate at surfaces and interfaces and thus alter the surface properties of matter. These materials are called surface-active agents or surfactants. Depending upon the manner in which they are used or the purpose they serve in specific applications, they may be referred to as detergents, emulsifying agents, foaming agents or foam stabilizers, antibacterial agents, fabric softeners, flotation reagents, antistatic agents, corrosion inhibitors, or by other names. There are two general ways of classifying surfactants. According to solubility, they are classified as water or oil soluble. The other classification is according to change type. Those that do not ionize are called nonionic surfactants. If they ionize and the surface-active ion is anionic, the material is an anionic surfactant. If the surface-active ion carries a positive charge, it is called a cationic surfactant.

Only molecules with certain specific types of configurations exhibit surface activity. In general, these molecules are composed of two segregated portions, one of which has low affinity for the solvent and tends to be rejected by the solvent. The other portion has sufficient affinity for the solvent to bring the entire molecule into solution. Water-soluble soaps are probably the oldest surfactants. The long hydrocarbon chain has a low affinity for water and is referred to as the hydrophobic or nonpolar portion of the molecule. The carboxylate group has a high affinity for water and is called the hydrophilic or polar portion.

SURFACE TENSION. Fluid surfaces exhibit certain features resembling the properties of a stretched elastic membrane; hence the term surface tension. Thus, one may lay a needle or a safety-razor blade upon the surface of water, and it will lie at rest in a shallow depression caused by its weight, much as if it were on a rubber air-cushion. A soap bubble, likewise, tends to contract, and actually creates a pressure inside, somewhat after the manner of a rubber balloon. The analogy is imperfect, however, since the tension in the rubber increases with the radius of the balloon, and the pressure inside, which would otherwise decrease, remains approximately constant; while the liquid “film tension” remains constant and the pressure in the bubble falls off as the bubble is blown.

Surface tension results from the tendency of a liquid surface to contract. It is given by the tension σ across a unit length of a line on the surface of the liquid. The surface tension of a liquid depends on the temperature; it diminishes as temperature increases and becomes 0 at the critical temperature. For water σ is 0.073 newtons/meter at 20°C, and for mercury, it is 0.47 newtons/meter at 18°C.

Surface tension is intimately connected with capillarity, that is, rise or depression of liquid inside a tube of small bore when the tube is dipped into the liquid. Another factor related to this phenomenon is the angle of contact. If a liquid is in contact with a solid and with air along a line, the angle θ between the solid-liquid interface and the liquid-air interface is called the angle of contact. See Fig. 1. If $\theta = 0$, the liquid is said to wet the tube thoroughly. If θ is less than 90°, the liquid rises in the capillary; and if more than 90°, the liquid does not wet the solid, but is depressed in the tube. For mercury on glass, the angle of contact is 140°, so that mercury is depressed when a glass capillary is dipped into mercury. The rise h of the liquid in the capillary is given by $h = 2\sigma\cos\theta/r\rho g$, where r is the radius of the tube, ρ the density of the liquid, and g is the acceleration due to gravity.

Surface tension can be explained on the basis of molecular theory. If the surface area of liquid is expanded, some of the molecules inside the liquid rise to the surface. Because a molecule inside a mass of liquid is under the forces of the surrounding molecules, while a molecule on the surface is only partly surrounded by other molecules, work is necessary to bring molecules from the inside to the surface. This indicates that force must be

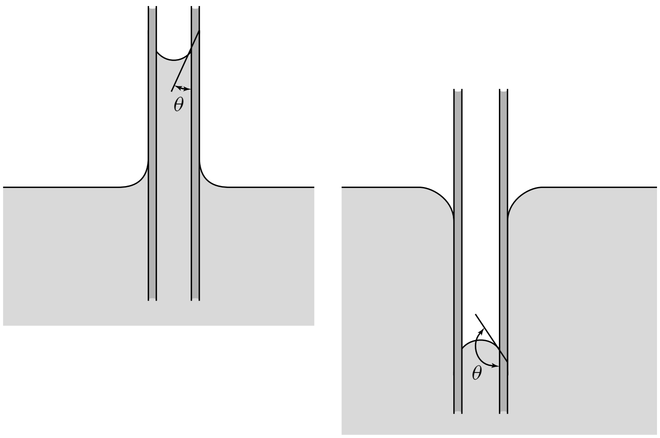

Fig. 1. Interrelationship between surface tension and capillarity: (*Left*) Case where angle theta is less than 90° (water); (*Right*) case where angle theta is greater than 90° (mercury)

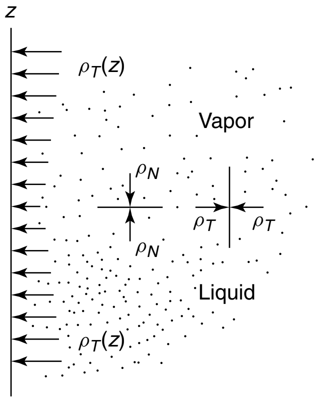

Fig. 2. Stress relationships in surface tension

applied along the surface in order to increase the area of the surface. This force appears as tension on the surface and when expressed as tension per unit length of a line lying on the surface, it is called the surface tension of the liquid.

The molecular theory of surface tension was dealt with by Laplace (1749–1827). But, as a result of the clarification of the nature of intermolecular forces by quantum mechanics and of the more recent developments in the study of molecular distribution in liquids, the nature and value of surface tension have been better understood from a molecular viewpoint. Surface tension is closely associated with a sudden, but continuous change in the density from the value for bulk liquid to the value for the gaseous state in traversing the surface. See Fig. 2. As a result of this inhomogeneity, the stress across a strip parallel to the boundary—ρ_N per unit area—is different from that across a strip perpendicular to the boundary—ρ_T per unit area. This is in contrast with the case of homogeneous fluid in which the stress across any elementary plane has the same value regardless of the direction of the plane.

The stress ρ_T is a function of the coordinate z, the z-axis being taken normal to the surface and directed from liquid to vapor. The stress ρ_N is constant throughout the liquid and the vapor. Figure 2 shows the stress ρ_N and ρ_T. The stress $\rho_T(z)$ as a function of z is also shown on the left side of the figure.

SURFACTANTS. The term surfactant, contraction of surface-active agent, is used to describe organic substances having certain characteristics in structure and properties. The term detergent is often used interchangeably with surfactant. As a designation for a substance capable of cleaning, detergent can also encompass inorganic substances when these do in fact perform a cleaning function. More often, however, detergent refers to a combination of surfactants and other substances, organic or inorganic, formulated to enhance functional performance, specifically cleaning, over that of the surfactant alone. It is so used herein.

Surfactants are characterized by the following features. Amphipathic structure: surfactant molecules are composed of groups of opposing solubility tendencies, typically an oil-soluble hydrocarbon chain and a water-soluble ionic group; solubility: a surfactant is soluble in at least one phase of a liquid system; adsorption at interfaces: at equilibrium, the concentration of a surfactant solute at a phase interface is greater than its concentration in the bulk of the solution; orientation at interfaces: surfactant molecules and ions form oriented monolayers at phase interfaces; micelle formation: surfactants form aggregates of molecules or ions called micelles when the concentration of the surfactant solute in the bulk of the solution exceeds a limiting value, the so-called critical micelle concentration (CMC), which is a fundamental characteristic of each solute–solvent system; and functional properties: surfactant solutions exhibit combinations of cleaning (detergency), foaming, wetting, emulsifying, solubilizing, and dispersing properties.

The presence of two structurally dissimilar groups within a single molecule is the most fundamental characteristic of surfactants. The surface behavior (surface activity) of the surfactant molecule is determined by the makeup of the individual groups, solubility properties, relative size, and location within the surfactant molecule.

Different designations describe the opposing groups within the surfactant molecules, e.g., hydrophobic (water hating) and hydrophilic (water liking), lipophobic (fat hating) and lipophilic (fat liking), oleophobic (fat (oil) hating) and oleophilic (fat (oil) liking), and lyophobic (solvent hating) and lyophilic (solvent liking). The terms polar and nonpolar are also used to designate water-soluble and water-insoluble groups, respectively.

Surface activity is not limited to aqueous systems; however, because water is present as the solvent phase in the overwhelming proportion of commercially important surfactant systems, its presence is assumed in much of the common terminology of industry. Thus, the water-soluble amphipathic groups are often referred to as solubilizing groups.

Surfactants are classified depending on the charge of the surface-active moiety. In anionic surfactants, this moiety carries a negative charge. In cationic surfactants, the charge is positive. In nonionic surfactants, there is no charge on the molecule, the solubilizing contribution can be supplied by side groups. Finally, in amphoteric surfactants, solubilization is provided by the presence of positive and negative charges in the molecule. In general, the hydrophobic group consists of a hydrocarbon chain containing ca 10–20 carbon atoms. The chain may be interrupted by oxygen atoms, a benzene ring, amides, esters, other functional groups, and/or double bonds. A propylene oxide hydrophobe can be considered a hydrocarbon chain in which every third methylene group is replaced by an oxygen atom. In some cases, the chain may carry substituents, most often halogens. Siloxane chains have also served as the hydrophobe in some surfactants.

Hydrophilic, solubilizing groups for anionic surfactants include carboxylates, sulfonates, sulfates, and phosphates. Cationics are solubilized by amine and ammonium groups. Ethylene oxide chains and hydroxyl groups are the solubilizing groups in nonionic surfactants. Amphoteric surfactants are solubilized by combinations of anionic and cationic solubilizing groups.

The molecular weight of surfactants may be as low as ca 200 up to the thousands for polymeric structures. A surfactant with a straight-chain C_{12}-hydrophobe and a solubilizing group is generally an effective structure. The optimum can be higher by several carbon atoms or even slightly lower than 12 depending on the nature of the polar group and the desired function of the surfactant.

In the application of surfactants, physical and use properties, precisely specified, are of primary concern. Chemical homogeneity is of little significance in practice. In fact, surfactants are generally polydisperse mixtures, such as the natural fats as precursors of fatty acid-derived surfactant structures; e.g., coconut oil contains glycerol esters of C_6–C_{18} fatty acids. Nonionic surfactants of the alcohol ethoxylate type are polydisperse not only with respect to the hydrophobe but also in the number of ethylene oxide units attached.

Commercial surfactants are complicated mixtures exceedingly difficult to separate into pure molecular species.

Physical Chemistry of Interfaces

The usefulness of surfactants stems from the effects that they exert on the surface, interfacial, and bulk properties of their solutions and the materials their solutions come in contact with.

Phenomena at Liquid Interfaces. The area of contact between two phases is called the interface; three phases can have only a line of contact, and only a point of mutual contact is possible between four or more phases. Combinations of phases encountered in surfactant systems are L–G, L–L–G, L–S–G, L–S–S–G, L–L, L–L–L, L–S–S, L–L–S–S–G, L–S, L–L–S, and L–L–S–G, where G = gas, L = liquid, and S = solid. An example of an L–L–S–G system is an aqueous surfactant solution containing an emulsified oil, suspended solid, and entrained air (see **Emulsions**; **Foam**). This embodies several conditions common to practical surfactant systems. First, because the surface area of a phase increases as particle size decreases, the emulsion, suspension, and entrained gas each have large areas of contact with the surfactant solution. Next, because interfaces can exist only between two phases, analysis of phenomena in the L–L–S–G system breaks down into a series of analyses, i.e., surfactant solution to the emulsion, solid, and gas. It is also apparent that the surfactant must be stabilizing the system by preventing contact between the emulsified oil and dispersed solid. Finally, the dispersed phases are in equilibrium with each other through their common equilibrium with the surfactant solution.

Figures 1**a** and 1**b** represent typical gas–liquid and liquid–liquid interfaces at equilibrium. Assuming that gas, G, consists of air and vapor of the liquid, L, at equilibrium, there is continuous movement of liquid molecules through the gaseous interfacial region R_G because rates of evaporation and condensation at the interface I_G are equal (Fig. 1). Liquid

molecules are also moving continuously into and out of I_G through the liquid interfacial region, R_L. R_G and R_L represent nonhomogeneous transitional regions between the homogeneous phases, G and L. Systems are known in which R_G and R_L have thicknesses equivalent to two or more layers of molecules, but for most analyses the interface I_G can be considered as consisting of a single layer of molecules.

For thermodynamic treatment of surface phenomena, the thickness of the boundary regions can often be ignored or their effect eliminated by selection of a convenient location for the interface I_{GL}. The liquid–liquid interface, I_{LL} (Fig. 1**b**) is similarly associated with interfacial regions, R_A and R_B, which can be treated like the gas–liquid interface in most analyses. Because few liquids are completely immiscible, mutual saturation is taken as the equilibrium condition.

Energy of Adhesion. The interfacial energy between two mutually insoluble saturated liquids, A and B, is equal to the difference in the separately measured surface energies of each phase: $\gamma_{AB} = \gamma_A - \gamma_B$, where γ is free-surface or interfacial energy. The term γ_{AB} represents the energy that must be added to the system to separate the liquids.

Contact Angle. The line of contact between the three phases of a G–L–S system is the locus of all points from which the angle of contact between the liquid and the solid can be measured. The drop of liquid, L, is resting on the solid, S, and both phases are exposed to the gas, G, at equilibrium saturation of the liquid in air (gas). The drop is assumed to be small enough for the flattening pressure of gravity to be negligible. The vector X_G is tangent to the liquid at its contact with the solid. The angle between the tangent and the surface of the solid is called the contact angle, θ. The equilibrium value of θ is an indicator of the energy relationships between liquid–liquid and liquid–solid interfaces.

Effects of Surfactants on Solutions. A surfactant changes the properties of a solvent in which it is dissolved to a much greater extent than is expected from its concentration effects. This marked effect is the result of adsorption at the solution's interfaces, orientation of the adsorbed surfactant ions or molecules, micelle formation in the bulk of the solution, and orientation of the surfactant ions or molecules in the micelles, which are caused by the amphipathic structure of a surfactant molecule. The magnitude of these effects depends to a large extent on the solubility balance of the molecule. An efficient surfactant is usually relatively insoluble as individual ions or molecules in the bulk of a solution.

Positive adsorption, the concentration of one component of a solution at a phase boundary, results in a lowering of the free-surface energy of the solution. Accumulation of a surfactant at a solution interface means that the attractive forces between surfactant and solvent are less than the attraction between solvent molecules. As thermal diffusion brings surfactant molecules into the surface, accumulation occurs because the solute molecules cannot re-enter the solution against the stronger mutual attraction of the solvent molecules. Negative adsorption occurs when the attraction between solute and solvent molecules is greater than that between solvent molecules, and exists in concentrated aqueous solutions of inorganic compounds such as NaOH. It is associated with a surface tension slightly higher than for pure water.

Practical applications of surfactants usually involve some manner of surfactant adsorption on a solid surface. This adsorption is always associated with a decrease in free-surface energy, the magnitude of which must be determined indirectly. The force with which the adsorbate is held on the adsorbent may be roughly classified as physical, ionic, or chemical. Physical adsorption is a weak attraction caused primarily by van der Waals forces. Ionic adsorption occurs between charged sites on the substrate and oppositely charged surfactant ions, and is usually a strong attractive force. The term chemisorption is applied when the adsorbate is joined to the adsorbent by covalent bonds or forces of comparable strength.

Physical and ionic adsorption may be either monolayer or multilayer. Capillary structures in which the diameters of the capillaries are small, i.e., one to two molecular diameters, exhibit a marked hysteresis effect on desorption. Sorbed surfactant solutes do not necessarily cover all of a solid interface and their presence does not preclude adsorption of solvent molecules. The strength of surfactant sorption generally follows the order cationic > anionic > nonionic.

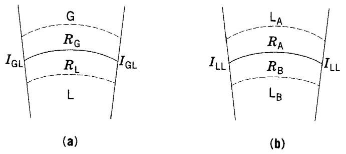

Fig. 1. (**a**) Gas–liquid (GL) interface; (**b**) liquid–liquid (LL) interface

Micelles. Surfactant molecules or ions at concentrations above a minimum value characteristic of each solvent-solute system associate into aggregates called micelles. The formation, structure, and behavior of micelles have been extensively investigated. The term critical micelle concentration (CMC) denotes the concentration at which micelles start to form in a system comprising solvent, surfactant, possibly other solutes, and a defined physical environment.

Micelle size is expressed as the micellar molecular weight or, more generally, the aggregation number, i.e., the number of monomers making up the micelles. Micellar aggregation numbers generally lie between 20 and 100, for single-chain anionic and cationic surfactants. Large aggregation numbers (>1000) have been reported for nonionic micelles, especially as the cloud point is approached.

Small micelles in dilute solution close to the CMC are generally believed to be spherical. Under other conditions, micellar materials can assume structures such as oblate and prolate spheroids, vesicles (double layers), rods, and lamellae.

Micellar properties are affected by changes in the environment, e.g., temperature, solvents, electrolytes, and solubilized components. These changes include complicated phase changes, viscosity effects, gel formation, and liquefication of liquid crystals.

Measurement of Surface Activity. Each surface-active property can be measured in a variety of ways and the method of choice depends on the characteristics of the substance to be tested. The most frequently determined properties are surface tension (γ_{SG}, γ_{LG}), interfacial tension (γ_{LL}, γ_{LG}), contact angle (θ), and CMC.

Anionic Surfactants

Carboxylate, sulfonate, sulfate, and phosphate are the polar, solubilizing groups found in most anionic surfactants. In dilute solutions of soft water, these groups are combined with a 12–15 carbon chain hydrophobe for best surfactant properties. In neutral or acidic media, or in the presence of heavy-metal salts, e.g., Ca, the carboxylate group loses most of its solubilizing power.

Of the cations (counterions) associated with polar groups, sodium and potassium impart water solubility, whereas calcium, barium, and magnesium promote oil solubility. Ammonium and substituted ammonium ions provide both water and oil solubility. Triethanolammonium is a commercially important example. Salts (anionic surfactants) of these ions are often used in emulsification. Higher ionic strength of the medium depresses surfactant solubility. To compensate for the loss of solubility, shorter hydrophobes are used for application in high ionic-strength media.

Carboxylates. Soaps represent most of the commercial carboxylates. The general structure of soap is $RCOO^-M^+$, where R is a straight hydrocarbon chain in the C_9–C_{21} range and M^+ is a metal or ammonium ion. Interruption of the chain by amino or amido linkages leads to other structures which account for the small volumes of the remaining commercial carboxylates.

Large volumes of soap are used in industrial applications as gelling agents for kerosene, paint driers, and as surfactants in emulsion polymerization. See also **Soaps**. Concern over water eutrophication resulted in a ban of phosphorus in laundry detergents. Phosphates have been effectively replaced by combinations of zeolite, citrate, and polymers, coupled with rebalanced synthetic active systems. Soap itself is generally present only as a minor component of surfactants.

Polyalkoxycarboxylates surfactants are produced either by the reaction of sodium chloroacetate with an alcohol ethoxylate or from an acrylic ester and an alcohol alkoxylate. Because of the presence of the ethylene oxide linkages, these products possess a higher aqueous solubility which manifests itself in greater compatibility with cationic surfactants and polyvalent cations.

N-Acylsarcosinates. Sodium N-lauroylsarcosinate is a good soaplike surfactant. The amido group in the hydrophobe chain lessens the interaction with hardness ions. N-Acylosarcosinates are prepared from a fatty acid chloride and sarcosine.

Acylated Protein Hydrolysates. These surfactants are prepared by acylation of protein hydrolysates with fatty acids or acid chlorides.

Acylated protein hydrolysates are mild surfactants recommended for personal-care products.

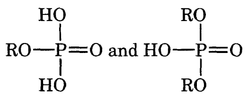
Sulfonates. The sulfonate group, $-SO_3M$, attached to an alkyl, aryl, or alkylaryl hydrophobe, is a highly effective solubilizing group. Sulfonic acid surfactants are strong, their salts are relatively unaffected by pH, they are stable to oxidation, and because of the strength of the C−S bond also stable to hydrolysis. Sulfonates interact moderately with the hardness, Ca^{2+} and Mg^{2+}, but significantly less so than carboxylates. Sulfates can be tailored for specific applications by introduction of double bonds or ester or amide groups, either into the hydrocarbon chain or as substituents. Because the introduction of the SO_3H function is inherently inexpensive, e.g., by oleum, SO_3, SO_2Cl_2, or $NaHSO_3$, sulfonates are heavily represented among high volume surfactants. See also **Sulfonation and Sulfation**.

Sulfonates include alkylbenzenesufonates (ABS), the most widely used of the non-soap surfactants; short-chain alkylarenesulfonates; lignosulfonates; napthalenesulfonates; α-olefinsulfonates; petroleum sulfonates; sulfonates with ester, amide, and ether linkages; and fatty acid ester sulfonates.

Sulfates and Sulfated Products. The sulfate group, $-OSO_3M$, where M is a cation, represents the sulfuric acid half-ester of an alcohol and is more hydrophilic than the sulfonate group because of the presence of an additional oxygen atom. Attachment of the sulfate group to a carbon atom of the hydrophobe through the C−O−S linkage limits hydrolytic stability, particularly under acidic conditions. Usage of sulfated alcohols and sulfated alcohol ethoxylates has expanded dramatically since the 1970s as the detergent industry reformulates consumer products to improve biodegradability, lower phosphate content, and move from powder to liquid.

Sulfates and sulfated products include alcohol sulfates, ethoxylated and sulfated alcohols; ethoxylated and sulfated alkylphenols; and sulfated natural oils and fats.

Phosphate Esters. Mono and diesters of orthophosphoric acid:



and their salts are useful surfactants. In contrast to sulfonates and sulfates, the resistance of alkyl phosphate esters to acids and hard water is poor. Calcium and magnesium salts are insoluble. In the acid form, the esters show limited water solubility, although their alkali metal salts are more soluble. The surface activity of phosphate esters is good, although in general it is somewhat lower than that of the corresponding phosphate-free precursors. Thus, a phosphated nonylphenol ethoxylated with 9 mol of ethylene oxide is less effective as a detergent in hard water than its nonionic precursor. At higher temperatures, however, the phosphate surfactant is significantly more effective.

Because of high costs and the limitations noted above, phosphate surfactants find application in specialty situations where such limitations are of no concern. As specialty surfactants, phosphate esters and their salts are remarkably versatile. Applications include emulsion polymerization of vinyl acetate and acrylates; dry-cleaning compositions where solubility in hydrocarbon solvents is a particular advantage; textile mill processing where stability and emulsifying power for oil and wax under highly alkaline conditions is necessary; and industrial cleaning compositions where tolerance for high concentrations of electrolyte and alkalinity is required. In addition, phosphate surfactants are used as corrosion inhibitors, in pesticide formulations, in papermaking, and as wetting and dispersing agents in drilling mud fluids.

Nonionic Surfactants

Unlike anionic or cationic surfactants, nonionic surfactants carry no discrete charge when dissolved in aqueous media. Hydrophilicity in nonionic surfactants is provided by hydrogen bonding with water molecules. Oxygen atoms and hydroxyl groups readily form strong hydrogen bonds, whereas ester and amide groups form hydrogen bonds less readily. Hydrogen bonding provides solubilization in neutral and alkaline media. In a strongly acid environment, oxygen atoms are protonated, providing a quasi-cationic character. Each oxygen atom makes a small contribution to water solubility; more than a single oxygen atom is therefore needed to solubilize a nonionic surfactant in water. Nonionic surfactants are compatible with ionic and amphoteric surfactants. Because a polyoxyethylene group can easily be introduced by reaction of ethylene oxide with any organic molecule containing an active hydrogen atom, a wide variety of hydrophobic structures can be solubilized by ethoxylation.

Polyoxyethylene Surfactants. Polyoxyethylene-solubilized nonionics (ethoxylates) are moderate foamers and do not respond to conventional foam boosters. Foaming shows a maximum as a function of ethylene oxide content. Low foaming nonionic surfactants are prepared by terminating the polyoxyethylene chain with less soluble groups such as polyoxypropylene and methyl groups. Ethoxylates can be prepared to attain almost any hydrophilic–hydrophobic balance. For incorporation into powdered products, they suffer from the disadvantage of being liquids or low melting waxes, which complicates the manufacture of free-flowing, crisp powders. Solid products are manufactured with ethoxylates of high ethylene oxide content. The latter, however, are too water soluble to provide good surface activity.

Base-catalyzed ethoxylation of aliphatic alcohols, alkylphenols, and fatty acids can be broken down into two stages: formation of a monoethoxy adduct and addition of ethylene oxide to the monoadduct to form the polyoxyethylene chain. Polyoxyethylene surfactants include alcohol ethoxylates and akylphenol ethoxylates.

Carboxylic Acid Esters. In the carboxylic acid ester series of surfactants, the hydrophobe, a naturally occurring fatty acid, is solubilized with the hydroxyl groups of polyols or the ether and terminal hydroxyl groups of ethylene oxide chains. Included in this group are glycerol esters; polyoxyethylene esters; and hydrosorbitol esters; ethoxylated anhydrosorbitol esters; natural ethoxylated fats, oils, and waxes; and glycol esters of fatty acids.

Carboxylic Amides. Carboxylic amide nonionic surfactants are condensation products of fatty acids and hydroxyalkyl amines. They include diethanolamine condensates, monoalkanolamine condensates, and polyoxyethylene fatty acid amides.

Fatty Acid Glucamides. Fatty acyl glucamides (FAGA) or polyhydroxyamides (PHA) have been adopted by detergent manufacturers in the United States and Europe. FAGA is produced via reaction of fatty acid methyl ester with N-methyl glucamine and attendant elimination of methanol. The methyl ester would be produced via the standard route of transesterification with fatty triglycerides; the glucamine, via reaction between glucose and methylamine with attendant hydrogenation and elimination of water.

Fatty acid glucamides are used in dishwashing liquids and heavy-duty liquids. Benefits include improved mildness for dishwashing liquids and improved enzyme stability in fabric washing detergents.

Polyalkylene Oxide Block Copolymers. The higher alkylene oxides derived from propylene, butylene, styrene, and cyclohexene react with active oxygens in a manner analogous to the reaction of ethylene oxide. Because the hydrophilic oxygen constitutes a smaller proportion of these molecules, the net effect is that the oxides, unlike ethylene oxide, are hydrophobic. The higher oxides are not used commercially as surfactant raw materials except for minor quantities that are employed as chain terminators in polyoxyethylene surfactants to lower the foaming tendency. The hydrophobic nature of propylene oxide units, $-CH(CH_3)CH_2O-$, has been utilized in several ways in the manufacture of surfactants.

Block polymer nonionic surfactants are not strongly surface-active but exhibit commercially useful surfactant properties. Aqueous solutions characteristically foam less than those of other surfactant types. They act as detergents, wetting and rinsing agents, demulsifiers and emulsifiers, dispersants, and solubilizers. They are used in automatic dishwashing detergent compositions, cosmetic preparations, spin finishing compositions for textile processing, metal-cleaning formulations, papermaking, and other technologies.

Cationic Surfactants. The hydrophobic moiety of a cationic surfactant carries a positive charge when dissolved in aqueous media, which resides on an amino or quaternary nitrogen. A single amino nitrogen is sufficiently hydrophilic to solubilize a detergent-range hydrophobe when protonated in dilute acidic solution; e.g., laurylamine is soluble in dilute hydrochloric acid. For increased water solubility, additional primary, secondary, or tertiary amino groups can be introduced or the amino nitrogen can be quaternized with low molecular weight alkyl groups such as methyl or hydroxyethyl. Quaternary nitrogen compounds are strong bases that form essentially neutral salts with hydrochloric and sulfuric acids. Most quaternary nitrogen surfactants are soluble even in

alkaline aqueous solutions. Polyoxyethylated amino surfactants behave like nonionic surfactants in alkaline solutions and like cationic surfactants in acid solutions.

Cationic surfactants are widely used in acidic aqueous and non-aqueous systems as textile softeners, conditioning agents, dispersants, emulsifiers, wetting agents, sanitizers, dye-fixing agents, foam stabilizers, and corrosion inhibitors. To some extent, the usage pattern mirrors that of the anionic surfactants in neutral and alkaline solutions. The positively charged cationic surfactants are more strongly adsorbed than anionic or nonionic surfactants on a variety of substrates including textiles, metal, glass, plastics, minerals, and animal and human tissue, which can often carry a negative surface charge. Substantivity of cationic surfactants is the key property in many applications. In general, they are incompatible with anionic surfactants. Reaction of the two large, oppositely charged ions gives a salt insoluble in water. Ethoxylation moderates the tendency to form insoluble products with anionic surfactants.

Many benzenoid quaternary cationic surfactants possess germicidal, fungicidal, or algicidal activity. Solutions of such compounds, alone or in combination with nonionic surfactants, are used as detergent sanitizers in hospital maintenance. Classified as biocidal products, their labeling is regulated by the U.S. EPA.

Amines. Aliphatic mono-, di-, and polyamines derived from fatty and main acids make up this class of surfactants. Primary, secondary, and tertiary monoamines with C_{18} alkyl or alkenyl chains constitute the bulk of this class. The products are sold as acetates, naphthenates, or oleates. Principal uses are as ore-flotation agents, corrosion inhibitors, dispersing agents, wetting agents for asphalt, and as intermediates for the production of more highly substituted derivatives.

In addition to the mono- and dialkylamines, representative structures of this class of surfactants include *N*-alkyltrimethylene diamine, $RNH(CH_2)_3NH_2$, where the alkyl group is derived from coconut, tallow, and soybean oils; or is 9-octadecenyl, 2-alkyl-2-imidazoline, where R is heptadecyl, heptadecenyl, or mixed alkyl, and 1-(2-aminoethyl)-2-alkyl-2-imidazoline, where R is heptadecyl, 8-heptadecenyl, or mixed alkyl.

This group includes amine oxides, ethoxylated alkylamines, 1-(2-hydroxyethyl)-2-imidazolines, and alkoxylates of ethylenediamine.

Amine oxides have attracted widespread interest as replacements for alkanolamides as foam builders in liquid hand-dishwashing compositions.

2-Alkyl-1-(2-hydroxyethyl)-2-imidazolines are used in hydrocarbon and aqueous systems as antistatic agents, corrosion inhibitors, detergents, emulsifiers, softeners, and viscosity builders. They are prepared by heating the salt of a carboxylic acid with (2-hydroxyethyl) ethylenediamine at 150–160°C to form a substituted amide; 1 mol water is eliminated to form the substituted imidazoline with further heating at 180–200°C. Substituted imidazolines yield three series of cationic surfactants: by ethoxylation to form more hydrophilic products; quaternization with benzyl chloride, dimethyl sulfate, and other alkyl halides; and oxidation with hydrogen peroxide to amine oxides.

Quaternary Ammonium Salts. The quaternary ammonium ion is a much stronger hydrophile than primary, secondary, or tertiary amino groups, strong enough to carry a hydrophobe into solution in the surfactant molecular weight range, even in alkaline media. The discrete positive charge on the quaternary ammonium ion promotes strong adsorption on negatively charged substrates, such as fabrics, and is the basis for the widespread use of these surfactants in domestic fabric-softening compositions. See also **Quaternary Ammonium Compounds**.

Amphoteric Surfactants

Amphoteric surfactants contain both an acidic and basic hydrophilic group. Ether or hydroxyl groups may also be present to enhance the hydrophilicity of the surfactant molecule. Examples of amphoteric surfactants include amino acids and their derivatives in which the nitrogen atom tends to become protonated with decreasing pH of the solution. Amino acid salts, under these conditions, contain both a positive and a negative charge on the same molecule.

Amphoteric surfactants are generally considered specialty surfactants, however, usage has expanded significantly. They do not irritate skin and eyes, exhibit good surfactant properties over a wide pH range, and are compatible with anionic and cationic surfactants. A basic nitrogen and an acidic carboxylate group are the predominant functional groups.

Imidazolinium Derivatives. Amphoteric imidazolinium derivatives are prepared from the 2-alkyl-1-(2-hydroxyethyl)-2-imidazolines and from sodium chloroacetate.

Imidazolinium derivatives are recommended as detergents, emulsifiers, wetting and hair conditioning agents, foaming agents, fabric softeners, and antistatic agents. There is some evidence that in cosmetic formulations certain imidazolinium derivatives reduce eye irritation caused by sulfate and sulfonate surfactants present in these products.

Uses

Detergency, i.e., cleaning, is the primary function of household and personal products. More recently, a secondary function, such as softening in combination with detergency in laundry detergents or conditioning in combination with detergency in shampoos, has been offered as an additional product benefit. In general, products have tended toward functional specialization.

Surfactants are widely used outside the household for a variety of cleaning and other purposes. Often the volume or cost of the surfactant consumed in industrial applications is small compared to benefit.

SUSPENSION. A system in which very small particles (solid, semisolid, or liquid) are more or less uniformly dispersed in a liquid or gaseous medium. If the particles are small enough to pass through filter membranes, the system is a colloidal suspension (or solution). Examples of solid-in-liquid suspensions are comminuted wood pulp in water, which becomes paper on filtration; the fat particles in milk; and the red corpuscles in blood. A liquid-in-gas suspension is represented by fog or by an aerosol spray. If the particles are larger than colloidal dimensions they will tend to precipitate if heavier than the suspending medium, or to agglomerate and rise to the surface if lighter. This can be prevented by incorporation of protective colloids. Polymerization is often carried out in suspension, the product being in the form of spheres or beads.

substances dates back to 2600 B.C. Sugar consumption varies considerably from one country to the next as shown in Table 1.

In terms of sugar consumption in the United States, until the early 1940s, sucrose from sugarcane and sugar beets accounted for a very high volume of the fundamental sweeteners. Since that time, there has been continuously increasing consumption of corn sweeteners and other caloric sweeteners, notably high-fructose corn syrup (HFCS). Of course, a marked impact on sucrose consumption occurred with the introduction of artificial sweeteners, particularly of saccharin and aspartame. Sweeteners fall into two general categories—*nutritive* and *nonnutritive*.

Nutritive Sweeteners

In addition to their sweetening power, nutritive sweeteners are effective preservatives in numerous foods. Sweeteners tie up water, essential for microorganism growth, thus preventing or inhibiting spoilage. Nutritive sweeteners also serve as food for yeasts and other fermenting agents, so important in many processes, including baking. The principal functional properties of sucrose are (1) browning reactions, (2) fermentability, (3) flavor enhancement, (4) freezing-point depression, (5) nutritive solids source, (6) osmotic pressure, (7) sweetness, (8) texture tenderizer, and (9) viscosity/bodying agent.

Among the principal *natural sugars* are fructose, glucose (also called dextrose), honey, invert sugar, lactose, maltose, raffinose and stachyose, sucrose, sugar alcohols, and xylitol.

Dextrose Equivalent. A means for comparing one sugar with another. The total amount of reducing sugars, expressed as dextrose (glucose), that is present in a given sugar syrup is calculated as a percentage of the total dry substance. More technically, the dextrose equivalent (DE) is the number of reducing ends of sugar that will react with copper. The DE can be measured in several ways.

Fructose. Also called *levulose* or *fruit sugar*, $C_6H_{12}O_6$. It is the sweetest of the common sugars, being from 1.1 to 2.0 times as sweet as sucrose. Fructose is generally found in fruits and honey. An apple is 4% sucrose, 6% fructose, and 1% glucose (by weight). A grape (*Vitis labrusca*) is about 2% sucrose, 8% fructose, 7% glucose, and 2% maltose (by weight) (Shallenberger). Commercially processed fructose is available as white crystals, soluble in water, alcohol, and ether, with a melting point between 103 and 105°C (217.4 and 221°F) (decomposition). Fructose can be derived by the hydrolysis of insulin; by the hydrolysis of beet sugar followed by lime separation; and from cornstarch by enzymic or microbial action.

Dry crystalline fructose is reported to have a sweetness level of 180 on a scale in which sucrose is represented at 100 (Andres, 1977). In cool, weak solutions and at lower pH, sweetness value is reported to be 140–150. At neutral pH or higher temperatures, the sweetness level drops, and at 50°C (122°F) sweetness equals that of a corresponding sucrose solution. A synergistic sweetness effect is reported between sucrose and fructose. A 40–60% fructose/sucrose mixture in a 100% water solution is sweeter than either component under comparable conditions (Unpublished report, University of Helsinki, 1972).

Glucose. Also known as *grape sugar* or *dextrose*, this is the main compound into which other sugars and carbohydrates are converted in the human body and thus is the major sugar found in blood. Glucose is naturally present in many fruits and is the basic "repeating" unit of the starches found in many vegetables, such as potato. Purified glucose takes the form of colorless crystals or white granular powder, odorless, with a sweet taste. Soluble in water, slightly soluble in alcohol. Melting point is 146°F (294.8°F). Glucose finds many uses—confectionery, infant foods, brewing and winemaking, caramel coloring, baking, and canning. Glucose is derived from the hydrolysis of corn starch with acids or enzymes. Glucose is a component of invert sugar and glucose syrup. Glucose was first obtained (1974) from cellulose by enzyme hydrolysis.

Corn (maize) syrup is a sweetener derived from corn starch by a process that was first commercialized in the 1920s. Corn syrup is composed of glucose and a variety of sugars described as the "maltose series of oligosaccharides." These syrups are not as sweet as sucrose, but are very often used in conjunction with sugar in confections and other food products.

Five types of corn sweeteners are commercially available: (1) *Corn syrup* (glucose syrup), with a DE of 20 or more, is a purified and concentrated aqueous solution of mono-, di-, and oligosaccharides. High fructose corn syrup (HFCS) is prepared by enzymatically converting glucose to fructose with glucose isomerase. (2) *Maltodextrin*, concentrated solutions or dried powders of disaccharides, characterized with a DE of less than 20. The manufacturing process is similar to that of corn syrup except that the conversion process is stopped at an earlier stage. (3) *Dried corn syrup* is a granular, crystalline, or powder product, from which a portion of the water has been removed. (4) *Dextrose monohydrate* is a purified and crystallized form of D-glucose, and contains one molecule of water of crystallization per molecule of D-glucose. (5) *Dextrose anhydrous* is primarily D-glucose with no water of crystallization.

Galactose. A monosaccharide commonly occurring in milk sugar or lactose. Formula, $C_6H_{12}O_6$.

Honey. A natural syrup which varies in composition and flavor, depending upon the plant source from which the nectar was collected by the honeybee, the amount of processing, and the duration of storage. The principal sugars contained in honey are fructose and glucose, the same components as in table sugar. There are minute amounts of vitamins and minerals in honey, but these are not usually considered in terms of calculating minimum requirements.

Invert Sugar. A mixture of 50% glucose and 50% fructose obtained by the hydrolysis of sucrose. Invert sugar absorbs water readily, and is usually only handled as a syrup. Because of its fructose content, invert sugar is levorotatory in solution, and sweeter than sucrose. Invert sugar is often incorporated in products where loss of water must be minimized. Commercially, invert sugar is obtained from the inversion of a 96% cane sugar solution. This sugar is used in various foods, in the brewing industry, confectionery field, and in tobacco curing.

Lactose. *Milk sugar* or *saccharum lactis*, $C_{12}H_{22}O_{11} \cdot H_2O$. Purified lactose is a white, hard, crystalline mass or white powder with a sweet taste, odorless. It is stable in air, soluble in water, insoluble in ether and chloroform, very slightly soluble in alcohol. The compound decomposes at 203.5°C (398.3°F). Lactose is derived from whey, by concentration and crystallization. Cow's milk contains about 5% lactose. Because of its relative lack of sweetening power, lactose is not considered a sweetener in the usual sense. It is used as a bulking agent in numerous food products. Lactose can be used effectively as a carrier for artificial sweeteners to give a free-flowing powder that is easily handled. There has been interest in the hydrolysis of lactose into glucose and galactose, both enzymatically and chemically. It has been reported that glucose and galactose are known to be sweeter than lactose itself. The relative sweetness of sugars is not a constant relationship, but depends upon many factors, including pH, temperature, and presence of other constituents. Mixtures of sugars can make a different sweetness impression than that of individual sugars alone. Synergistic sweetness often results from a combination of sugars.

Maltose. Also known as *malt sugar*, maltose is a product of the fermentation of starches by enzymes or yeast. Barley malt, which is used as an adjunct in brewing, enhances the flavor and color of beer because of its maltose content. Maltose also is formed by yeast during breadmaking. Maltose is the most common reducing disaccharide, $C_{12}H_{22}O_{11} \cdot H_2O$, composed of two molecules of glucose. It is found in starch and

glycogen. Purified maltose takes the form of colorless crystals, melting point, 102–103°C (215.6–217.4°F). Soluble in alcohol; insoluble in ether. Combustible. Maltose is used as a nutrient, sweetener, and culture medium.

Raffinose and Stachyose. These are sugars found in significant amounts in some foods, such as beans. These sugars are not digested in the stomach and upper intestine as are other disaccharides. They are fermented by bacteria in the lower digestive tract, producing gases and sometimes causing discomfort from flatulence. Raffinose is a trisaccharide composed of one molecule each of D(+)-galactose, D(+)-glucose, and D(−)-fructose, $C_{18}H_{32}O_{16} \cdot 5H_2O$. Raffinose is sometimes used in the preparation of other saccharides.

Sucrose. Table sugar, also known as *saccharose*. Sucrose is a disaccharide, composed of two simple sugars, glucose and fructose, chemically bound together, $C_{12}H_{22}O_{11}$. Hard, white, dry crystals, lumps, or powder. Sweet taste, odorless. Soluble in water; slightly soluble in alcohol. Solutions are neutral to litmus. Decomposes in range of 160–186°C (320–366.8°F). Combustible. Optical rotation = +33.6°. Derived from sugarcane or sugar beets and also obtainable from sorghum. Sucrose is the most abundant free sugar in the plant kingdom and has been used since antiquity (Mead and Chem, 1977).

Turbinado sugar is raw sugar that has been refined to remove impurities and most of the molasses. It is edible when produced under sanitary conditions and has a molasses flavor. *Brown sugar* consists of sucrose crystals covered with a film of molasses syrup that give the characteristic color and flavor. The sucrose content varies from 91 to 96%. *Confectioner's* or *powdered sugar* is another form of sucrose made by grinding the sugar crystals. It is usually mixed with about 3% starch to prevent clumping. It is used for household baking, canning, and table use, or industrially where rapid solution in cold liquids is desirable.

Sugar Alcohols. These are polyols, chemically reduced carbohydrates. Important in this group are *sorbitol, mannitol, maltitol*, and *xylitol*. Xylitol is described later.

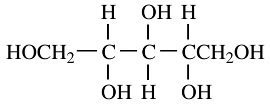
Polyols are frequently used sugar substitutes and are particularly suited to situations where their different sensory and functional properties are attractive. In addition to sweetness, some of the polyols have other useful properties. For example, although it contains the same number of calories/gram as other sweeteners, sorbitol is absorbed more slowly from the digestive tract than is sucrose. It is, therefore, useful in making foods intended for special diets. When consumed in large quantities (1–2 oz; 25,059 g)/day, sorbitol can have a laxative effect, apparently because of its comparatively slow intestinal absorption.

When sugar alcohols are ingested, the body converts them first to fructose, which does not require insulin to facilitate its entry into the cells. For this reason, ingesting these sweeteners (including fructose itself) does not cause the immediate increase in blood sugar level which occurs upon eating glucose or sucrose. Within the body, however, the fructose is rapidly converted to other compounds, which *do* require insulin in their metabolism. One effect of this stepwise metabolism is to "damp out" the peaks in blood sugar levels which occur immediately after ingesting sucrose, but which are absent after ingesting fructose, even if the eventual insulin requirements are the same. Thus, individuals with metabolic problems should not make the assumption that fruit sugars are perfectly all right to consume, but first should consult their physicians. In fact, some health scientists are dubious about pursuing the apparent claims for substituting fructose and sugar alcohols for sucrose as a major sweetener, particularly for diabetics, until more research is done on their long-range nutritional and biophysiological consequences. Research interest has also focused on these sweeteners because of their relatively low potential for causing dental caries. Studies have shown about a 30% reduction in dental caries in laboratory animals on sorbitol and mannitol diets, and virtually complete elimination of caries in the animals when on xylitol diets.

Xylitol. This is a 5-carbon sugar alcohol that occurs widely in nature—raspberries, strawberries, yellow plums, cauliflower, spinach, and many other plants. Although widely distributed in nature, it is present in low concentrations and this makes it uneconomic to extract the substance directly from plants. Thus, commercial xylitol must be produced from xylan or xylose-rich precursors through the use of chemical, enzymatic, and other bioprocessing conversions. A frequently used source has been birch tree chips. Other appropriate starting materials include beech and other hardwood chips, almond and pecan shells, cottonseed hulls, straw, cornstalks (maize), and corn cobs. The base source in the aforementioned agricultural waste materials is hemicellulose xylan. The hemicellulose is acid hydrolyzed to yield xylose which, followed by hydrogenation and chromatographic separation, yields xylitol.

Xylitol is equally as sweet as sucrose. This property is of advantage to food processors because in reformulating a product from sucrose to xylitol, approximately the same amounts of xylitol can be used. Because xylitol has a negative heat of solution, the substance cools the saliva, producing a perceived sensation of coolness, quite desirable in some food products, notably beverages. Recently, this property has been used in an iced-tea-flavored candy distributed in the European market. As of the late 1980s, 28 countries have ruled positively in terms of xylitol for use in commercial products. Xylitol has been found particularly attractive for use in chewing gum, mint and hard candies, and as a coating for pharmaceutical products. Xylitol has the structural formula shown below, with a molecular weight of 152.1. It is a crystalline, white, sweet, odorless powder, soluble in water and slightly soluble in ethanol and methanol. It has no optical activity.

Isomalt. Developed in Germany, isomalt is described as an energy-reduced bulk sweetener and marketed in Europe under the tradename *Palatinit™mark*. The compound is produced from sucrose in a two-step process, as shown in Fig. 1.



In the first step, the easily hydrolyzable 1–2 glucoside linkage between the glucose and fructose moieties of sucrose are catalyzed by immobilized enzymes to produce isomaltulose, *Palatinos.™ mark* After crystallization, the isomaltulose is hydrogenated in a neutral aqueous solution using a nickel catalyst.

It is claimed that isomalt is odorless, white, crystalline, and sweet tasting without the accompanying taste or aftertaste. Sweetening power is from 0.45 to 0.6 that of sucrose. A synergistic effect is achieved when isomalt is combined with other artificial sweeteners and sugar substitutes. Principal applications are in confections, pan-coated goods, and chewing gum. The substance was approved for use in most European countries in 1985. Classification of isomalt as a GRAS substance was petitioned in the United States. (GRAS = generally regarded as safe.)

Aspartame. This synthetic sweetener is included with the nutritive sweeteners because it does have some caloric value (when metabolized as a protein, it releases 4 kcal/g). The relationship between sweetness of aspartame and sucrose is almost linear when plotted on a log-log scale. Aspartame is 182 times sweeter than a 2% sucrose solution, but only 43 times sweeter than a 30% solution. The clean, full sweetness of aspartame is similar to that of sucrose and complements other flavors.

The full name of aspartame is *aspartylphenylalanine*, a dipeptide that degrades to a simple amino acid. It has been reported as easily metabolized by humans. Aspartame was accidentally discovered in 1965 with the synthesis of a product for ulcer therapy. Aspartame is metabolized by the same biochemical pathway as proteins, yielding phenylalanine, aspartic acid, and methanol. Because of the byproduct phenylalanine, which some individuals are unable to metabolize, appropriate labeling is required. This is a concern for individuals with phenylketonuria (PKU). Aspartame was first approved in the United States in 1974, then banned in 1975. In July of 1981, it was approved for use in various foods, dry beverage mixes, and in tabletop sweeteners. Approval for use in carbonated beverages was granted in July 1983.

Currently, aspartame is used in tabletop sweeteners (*Equal* in the U.S.; *Egal* in Quebec, Canada; and *Canderal* in Europe and the U.K.). Aspartame currently is incorporated as the exclusive sweetening ingredient in nearly all diet soft drinks in the United States. In other countries, it may be blended with saccharin at a level close to 50% of the saccharin level. Soft-drink manufacturers have taken some measures to enhance stability by raising pH slightly and by more closely controlling the inventory for carbonated soft drinks. Notable differences in sweetness are perceived at a 40% loss in aspartame level.

Crystalline Maltitol. Classified as a bulk sweetener with taste and mouthfeel similar to sucrose, crystalline maltitol contains maltitol as the major component (88+%), with small amounts of sorbitol, maltotriitrol, and hydrogenated oligosaccharides. Its use is in tabletop sweeteners, chocolate, candy, and baked goods. Maltitol has been a major component of hydrogenated glucose syrup in the United States since 1977 and has been

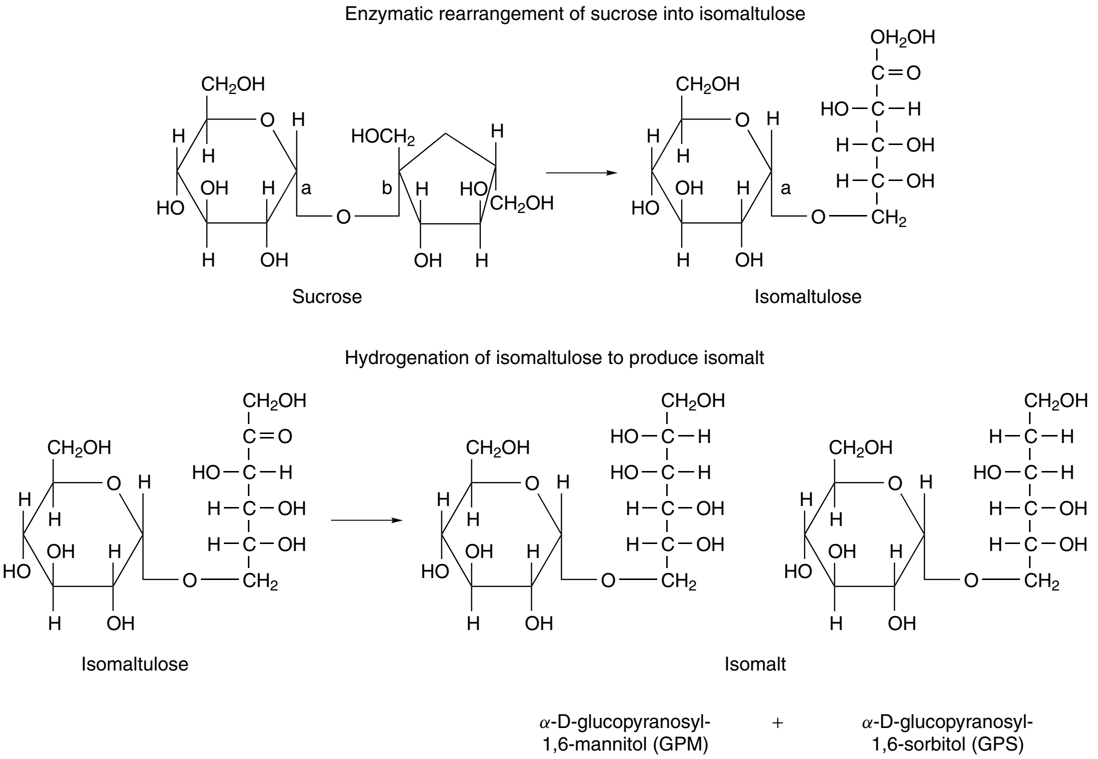


Fig. 1. Isomalt

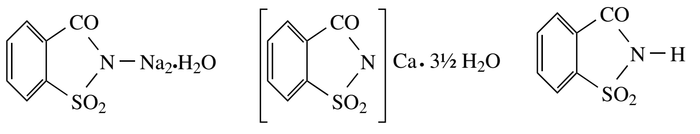
used in Japan since 1963. The product was introduced in Europe in 1984. Classification of crystalline maltitol as a GRAS substance was petitioned in the United States in 1986.

Nonnutritive Sweeteners

There are several currently used and a number of potential noncaloric sweeteners, including saccharin, cyclamate (banned in the U.S., but permitted in approximately 40 other countries), acesulfame K, monellin (from the serendipity berry), stevioside, glycyrrhizin, hernandulcin, neosugar, miraculin (from miracle fruit), and a sweetener-enhancer, thaumatin, are being investigated.

Saccharin. A noncaloric sweetener that is about 300 times as sweet as sugar. The compound is manufactured on a large scale in several countries. It is made as saccharin, sodium saccharin, and calcium saccharin, as shown by formulas below.



Sodium saccharin | Calcium saccharin | Saccharin

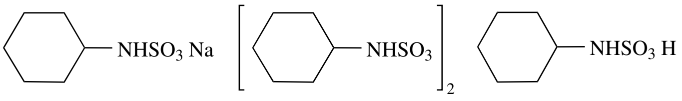
Saccharin (ortho-benzosulfimide) was discovered in 1879 by I. Remsen and C. Fahlberg when they were researching the oxidation products of toluene sulfone amide. The most common forms of saccharin are sodium and calcium saccharin, although ammonium and other salts have been prepared and used to a very limited extent. The saccharins are white, crystalline powders, with melting points between 226 and 230°C (438.8 and 446°F). Soluble in amyl acetate, ethyl acetate, benzene, and alcohol; slightly soluble in water, chloroform, and ether. Saccharin is derived from a mixture of toluenesulfonic acids. They are converted into the sodium salts, then distilled with phosphorus trichloride and chlorine to obtain the ortho-toluene sulfonyl chloride, which by means of ammonia is converted into ortho-toluenesulfamide. This is oxidized with permanganate, then treated with acid, and saccharin is crystallized out. In food formulations, saccharin is used mainly in the form of its sodium and calcium salts. Sodium bicarbonate may be added to provide improved water solubility.

Saccharin is used in conjunction with aspartame in carbonated beverages. Other uses include tabletop sweeteners, dry beverage blends, canned fruits, gelatin desserts, cooked and instant puddings, salad dressings, jams, jellies, preserves, and baked goods.

For many years, saccharin has been under investigation by a number of countries. As of the late 1900s, some questions remained unresolved.

Cyclamate. Group name for synthetic, nonnutritive sweeteners derived from cyclohexylamine or cyclamic acid. The series includes sodium, potassium, and calcium cyclamates. Cyclamates occur as white crystals, or as white crystalline powders. They are odorless and in dilute solution are about 30 times as sweet as sucrose. The purity of commercially available compounds is approximately 98%.

Discovered in 1937 and patented in 1940, cyclamate is a derivative of cyclohexylamine, specifically, cyclohexane sulfonic acid. The sodium salt form is normally used, but the calcium salt may be substituted in low-sodium diets. See structural formulas below.

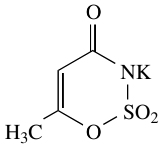


Sodium cyclamate | Calcium cyclamate | Cyclamic acid

Once widely used, cyclamate was prohibited in the United States in 1970. Although used in many other countries, reapproval in the United States has not yet been established. An independent review of the possible carcinogenicity of cyclamate was conducted in April 1985 by the National Academy of Sciences/National Research Council at the request of the Food and Drug Administration. The review concluded that cyclamate itself is not a carcinogen, although it may serve as a promotor or cocarcinogen in the presence of other substances.

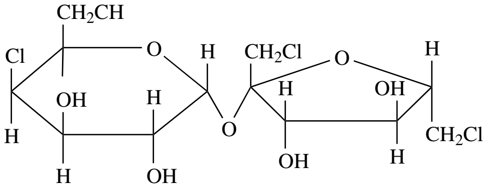
Acesulfame-K. This substance (potassium salt of the cyclic sulfanomide), 6-methyl-1,2,3-oxathiazine-4(3H)-1,2,2-dioxide, shown below, was developed by Karl Clauss (Hoechst Celanese Corporation, Somerville, New Jersey) in 1967. The compound is a white, odorless, crystalline substance with a sweetening power 200 times that of sucrose. A synergistic effect is produced when the substance is combined with a number of other sweeteners. The substance is calorie-free and not metabolized in the human body. Approval of the use of Acesulfame-K was given by the Food and Drug Administration (FDA) in the United States in 1983 and it is found in scores

of popular retail products, including yogurt, rice pudding, and soft drinks.



Acesulfame-K

Sucralose. Developed in England during the mid-1980s, testing and evaluation commenced in 1988. The structural formula of the compound (a chlorinated disaccharide derived from sucrose) is shown below.



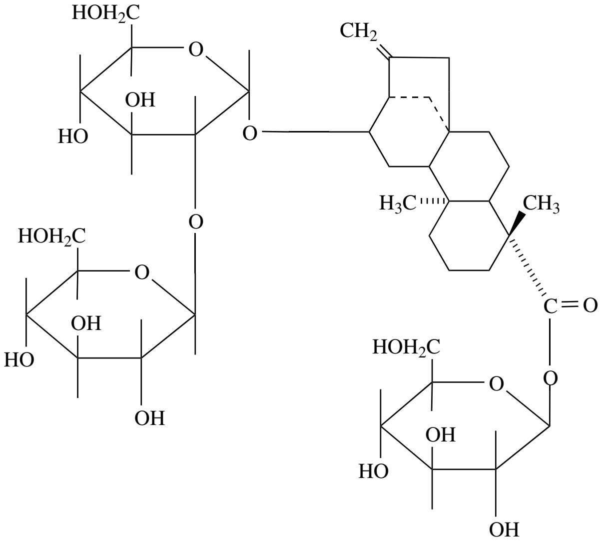
Sucralose

Sucralose is absorbed poorly in humans and other mammalian species. The small portion that is absorbed is not broken down and is quickly excreted. It has been reported that an extensive array of studies has demonstrated that sucralose is nontoxic—not carcinogenic, teratogenic, mutagenic, or caloric.

Monellin. The sweetness of this compound is claimed to be 1500 to 3000 times that of sucrose, but a different flavor profile prevails. The detection of a sweet taste is slow, commencing after a few seconds in contact with the taste buds, then gradually increasing to its peak intensity. The sweet taste can persist for up to an hour. The source is the relatively rare serendipity berry, the fruit of a noncultivated West African vine. Extraction of the sweet component is effected by treating the berry with a series of enzymes (pectinase and bromelain), followed by dialysis and chromatographic separation. The compound resulting contains the protein *monoellin* with a molecular weight of about 10,700 and composed of two nonidentical polypeptide chains of 50 and 43 amino acids. Neither of the individual chains imparts sweetness. Regulatory measures have not been instituted because of the compound's apparent instability and limited raw resources for processing. However, to date, tests with mice have shown no evidence of toxicity.

Stevioside. Derived from the roots of the herb *Stevia rebaudiana*, this compound has found limited use in Japan and a few other countries as a low-calorie sweetener having about 300 times the sweetening power of sucrose. The compound has not been investigated thoroughly by a number of countries with strong regulatory agencies and, therefore, is not on the immediate horizon for wide consideration as a sweetener.

The dried leaves of *S. rebaudiana* have been used in Paraguay for many years to sweeten bitter drinks. From 3 to 8% of the dried leaves is stevioside, which is a diterpene glycoside as shown by the formula below.



Stevioside

Glycyrrhizins. These are noncaloric sweeteners approximately 50 times as sweet as sugar and used as a flavor enhancer under the GRAS classification in the United States. Glycyrrhizins, which have a pronounced licorice taste, are used in tobacco, pharmaceuticals, and some confectionary products. They are available in powder or liquid form and with color, or as odorless, colorless products. These compounds are stable at high temperatures (132°C; 270°F) for a short time and thus can be used in bakery products. In some chocolate-based products, the sweetener has been used to replace up to 20% of the cocoa. The sweetener also has excellent foaming and emulsifying action in aqueous solutions. Typical products in which these sweeteners may have application include cake mixes, ice creams, candies, cookies, desserts, beverages, meat products, sauces, and seasonings, as well as some fruit and vegetable products. Generally available as malted and ammoniated glycyrrhizin.

The basic compound is a triterpene glycoside. It is extracted from the licorice root, of which the principal sources are China, Russia, Spain, Italy, France, Iran, Iraq, and Turkey. The roots, containing 10% moisture, are dried and shredded, after which they are extracted with aqueous ammonia, concentrated in vacuum evaporators, precipitated with sulfuric acid, and crystallized with 95% ethyl alcohol.

Hernandulcin. Tasting panels have estimated that this substance is 1000 times sweeter than sucrose, but the flavor profile is described as somewhat less pleasant than that of sucrose. Hernandulcin is derived from a plant, *Lippia dulcis* Trev, commonly known as "sweet herb" by the Aztecs as early as the 1570s. It has been categorized as noncarcinogenic, based upon standard bacterial mutagenicity tests. The economic potential is being studied.

Neosugar. This is another substance in early stages of development and testing. The compound is composed of sucrose attached in a beta(2-1) linkage to 2, 3, or 4 fructose units.

Miraculin. Rather than a sweet-tasting substance, miraculin is described as a taste-modifying substance that elicits a sweet taste to tart foods. The product has been reported as used by African cultures for over a century. The compound is derived from a shrub (*Synsepalum dulcificum*) which grows in West Africa. Miraculin is a glycoprotein with a molecular weight ranging from 42,000 to 44,000. Approval of the Food and Drug Administration has thus far been denied, awaiting further tests. A GRAS category was denied in 1974.

Thaumatin. This is a protein extracted and purified from *Thaumatococcus danielli*, a plant that is found in West Africa. The leaves of the plant have been used for many years in Africa for wrapping food during cooking. Claims have been made that thaumatin is from 2000 to 2500 times sweeter than 8–10% solution of sucrose. The final product is odorless, cream-colored and imparts a lingering licorice-like aftertaste. The substance synergizes well with monosodium glutamate (MSG) and is used in typical Japanese seasonings as well as in chewing gum, pet foods, and certain pharmaceuticals (to mask unpleasant flavor notes). Use in Japan has been approved since 1979. It is considered a GRAS substance in the United States for use in chewing gum. In this application, thaumatin extends the flavor and boosts the perceived duration of flavor. The compound is normally applied as a dust to the surface of gum. Some authorities believe that the use of thaumatin in pet foods has high potential.

Sweeteners in Formulating and Processing

In using low-calorie sweeteners in various food products, the problems are not limited to flavor, but often much more importantly involve texture, acidity, storage stability, and preservability, among others. Acceptable nonnutritively sweetened products cannot be developed by the simple substitution of artificial sweeteners for sugars. Rather, the new product must be completely reformulated from the beginning. Three examples follow.

Jams, Jellies, and Preserves. Traditional products in this category contain 65% or more soluble solids. In low-calorie analogs, soluble solids range from 15% to 20%. Under these circumstances, commonly used pectins (high methoxyl content) do not suffice. Thus, special LM (low methoxyl) pectins must be used, along with additional gelling agents, such as locust bean gum, guar gum, and other gums and mucilagenous substances, some of which may require some masking. In the absence of sugar, a preservative, such as ascorbic acid, sorbic acid, sorbate salts, propionate salts, and benzoates, usually is required to the extent of about 0.1% (weight).

Soft Drinks. In addition to providing sweetness, sugar also functions to provide mouthfeel and to stabilize the carbon dioxide of soft drinks. To contribute to mouthfeel, the use of hydrocolloids and sorbitol has been attempted with limited success. Hydrocolloids also help to some degree with the problem of carbonation retention, but the principal solutions to this problem involve avoiding all factors which contribute to carbonation loss. Thus, the requirement for very well filtered water to eliminate particulates as possible nucleation points; any substances that promote foaming must be avoided; any emulsifying agents used in connection with flavoring agents must be handled carefully to avoid foaming; carbonation should be carried out at low temperature (34°F; 1.1°C); and trace quantities of metals must be absent from the water.

Bakery Products. These foods are among the most difficult as regards the use of artificial sweeteners. A listing of the functions of sugar in baked goods beyond that of providing sweetness is indicative of these problems. Sugar contributes to texture in forming structures, in providing moist and tender crumbs by counteracting the toughening characteristics of flour, milk, and egg solids. In the emulsification process required to retain gas during leavening, sugar is an effective accessory agent. Ingredients frequently used in bakery products to compensate for the absence of sugar include carboxymethylcellulose, mannitol, sorbitol, and dextrins, but, generally, these have not been very satisfactory—either to processor or consumer. This remains a large area of challenge for the food processors and ingredient manufacturers.

Evaluating Synthetic Sweeteners. Evaluation of new sweeteners, unlike that of most functional food ingredients, is not possible using totally objective means. There are no general rules leading to structure/function relationships for all classes of sweeteners. The principal judgments must rely on human sensory panel tests. The training and administration of sensory panels for sweeteners are beyond the scope of this volume.

SYENITE. A coarse-grained, granular, therefore intrusive, igneous rock of the general composition of granite except that quartz is either absent or present in a relatively small amount. The feldspars are alkaline in character and the dark mineral is usually hornblende. Soda-lime feldspars may be present in small quantities. The term syenite was originally applied to hornblende granite like that of Syene in Egypt from whence the name is derived. Syenite is not a common rock, some of the more important occurrences being, in the United States, in New England, Arkansas, Montana, and New York State (syenite gneisses), and elsewhere, in Switzerland, Germany, and Norway.

SYLVANITE. A mineral, a telluride of gold and silver approximating the formula $AgAuTe_4$. Sylvanite is monoclinic, occurring in bladed, columnar, and granular forms as well as arborescent and branching. It is a brittle mineral; hardness, 1.5–2; specific gravity, 8.16; luster, metallic; color and streak, steel gray to yellowish-gray. This mineral is found associated with gold and tellurides of gold and silver or with sulfides such as pyrite. It is found in Rumania, Australia, Colorado and California. It was named for Rumanian Transylvania where it was first found.

Krennerite is another telluride of gold and silver with a similar composition to sylvanite, but crystallizing in the orthorhombic system. Calaverite is a gold telluride with only a small silver content.

SYLVITEA. A mineral, potassium chloride, KCl, occurring in cubes, or as cubes modified by octahedra. Sylvite is therefore isometric. It has a perfect cubic cleavage; uneven fracture; is brittle; hardness, 2; specific gravity, 1.9; luster, vitreous; colorless when pure but may be white, bluish, yellowish or reddish due to impurities. It is soluble in water. It is much rarer than halite and has been found as sublimates at Mt. Vesuvius and as bedded deposits at Stassfurt, Germany. Extensive deposits occur in sedimentary deposits in the Permian basin of southwestern New Mexico, near Carlsbad, in the United States.

It is used as a source of potash salts. Potassium chloride was called by the early chemists *sal digestivus Sylvii*, whence the name of the mineral.

SYMMETRY. Arrangement of the constituents of molecule in a definite and continuously repeated space pattern or coordinate system. It is described in terms of three parameters called elements of symmetry. (1) The center of symmetry, around which the constituent atoms are located in an ordered arrangement; there is only one such center in a molecule, which may or may not be an atom. (2) Planes of symmetry, which represent division of a molecule into mirror-image segments. (3) Axes of symmetry, represented by lines passing through the center of symmetry; if the molecule is rotated it will have the same position in space more than once in a complete 360-degree turn, e.g., the benzene molecule with 6 axes of symmetry requires 60-degree rotation to return to its identical position.

See also **Stereochemistry**.

SYNDETS. See **Detergents**.

SYNERESIS. The contraction of a gel with accompanying pressing out of the interstitial solution or serum. Observed in the clotting of blood, with silicic acid gels, etc. See also **Colloid Systems**.

SYNGE, RICHARD L. M. (1914–1994). An Irish mathematician and physicist who won the Nobel prize for chemistry in 1952 along with Archer J. P. Martin for their invention of partition chromatography. His research was on the application of methods of physical chemistry to isolate and analyze proteins, with special attention to antibiotic peptides and higher plants. He received his doctorate from Cambridge.

SYNTHESIS (Chemical). The process of building chemical compounds through a planned series of steps (reactions, separations, etc.). Synthesis usually is the method of choice: (1) when the desired compound is not

present in natural materials from which it can be isolated: (2) when the compound cannot be easily obtained from reacting readily available materials in a few simple steps; and (3) although a compound may be available within a natural complex, the economic separation and purification are prohibitive, or often in the case of biochemicals, too little natural raw material is available to meet the demand.

Even more important, synthesis plays a key role in developing new, untried chemical structures which, on paper, appear to have properties that may be of great value, e.g., a new synthetic material, a new drug, or a new fuel. Chemicals by design from prior knowledge of related materials generally are created via the route of synthesis. Further, synthesis is fundamental to broadening the base of chemical knowledge. Sometimes unexpected results occur, i.e., compounds with unusual, unexpected, and often desirable practical chemical and/or physical properties.

Because of the hundreds of thousands of organic substances already established, but many yet remaining to be "built," organic synthesis predominates. Most of the synthetics (elastomers, fibers, and other polymers, coatings, films, adhesives, and numerous other products) that have appeared during the last 30 to 40 years resulted from research involving organic synthesis. Some of the early work in organic synthesis dealt with the creation of certain fatty acids and ketones. A few examples are given to provide an insight into the workings of synthesis.

In the following examples, only the main starting ingredients and products are shown. No attempt is made to indicate byproducts or the conditions of the reactions involved:

(a) Target compound: Ethylpropylacetic acid, $(C_2H_5)(C_3H_7)CH{:}COOH$

(1) Acetic anhydride → ethyl acetate
(+ alcohol)
(2) Ethyl acetate → ethyl acetoacetate
(sodium + dilute acids)
(3) Ethyl acetoacetate → sodium derivative of ethyl acetoacetate
(+ sodium ethoxide)
(4) Sodium derivative of ethyl acetoacetate → ethyl ethylpropyl acetoacetate
(+ propyl iodide)
(5) Ethyl ethylpropyl acetoacetate → ethylpropylacetic acid
(concentrated alcohol and potash)

(b) Target compound: Butyl acetone, $CH_3 \cdot CO \cdot CH_2 \cdot C_2H_4$
(1) through (3), same as given in example (a)
(4) Sodium derivative of ethyl acetoacetate → ethylbutylpropyl acetoacetate
(+ butyl iodide)
(5) Ethylbutylpropyl acetoacetate → butyl acetone
(+ dilute alcohol and potash)

(c) Target compound: *n*-valeric acid, $CH3 \cdot CH_2 \cdot CH_2CH_2COOH$

(1) Potassium chloroacetate → potassium cyanoacetate
(+ potassium cyanide)
(2) Potassium cyanoacetate → ethyl malonate
(+ alcohol and hydrogen chloride)
(3) Ethyl malonate → sodium derivative of ethyl malonate
(+ sodium ethoxide)
(4) Sodium derivative of ethyl malonate → ethylpropyl malonate
(+ propyl iodide)

The compounds on the right-hand side of intermediate reactions are often called *intermediates*. See also **Intermediate (Chemical)**.

Some of the notable syntheses from the early history of the technique include:

Inorganic Syntheses	
1746	Sulfuric acid (chamber process)
1800	Soda ash (Le Blanc process)
1861	Soda ash (Solvay process)
1890	Sulfuric acid (contact process)
1912	Ammonia (Haber-Bosch process)
Organic Syntheses	
1828	Urea (Wohler)
1857	Mauveine (Perkin)
1869	Celluloid (Hyatt)
1877	Ethylbenzene (Friedel-Crafts)
1884	Rayon (Chardonnet)
1910	Phenolic resins (Baekeland)
1910	Neoarsphenamine (Ehrlich)
1920	Aldehydes, alcohols (Oxo synthesis)
1925	Insulin (Banting)
1927	Methanol
1930	Neoprene (Nieuwland)
1935	Nylon (Carothers)
1940	Styrene-butadiene rubber
1950	Polyisoprene

SYNTHESIS GAS. For a number of industrial organic syntheses that proceed in the gaseous phase, it is advantageous to prepare a chargestock to specification. When a mixture of gases is so prepared, the term *synthesis gas* is often used. Thus, there are several mixtures which qualify under this definition: (1) a mixture of H_2 and N_2 used for NH_3 synthesis; (2) a mixture of CO and H_2 for methyl alcohol synthesis; and (3) a mixture of CO, H_2, and olefins for the synthesis of oxo-alcohols. Ammonia synthesis gas is described briefly here.

The hydrogen required for NH_3 synthesis gas may be obtained in commercial quantities from coke oven water gas; from steam reforming of hydrocarbons; from the partial oxidation of hydrocarbon chargestocks; or from the electrolysis of H_2O. The nitrogen required may come from the introduction of air to the process, or where specifically required, pure nitrogen may be obtained from an air separation plant. Since NH_3 synthesis occurs under high pressure, it is advantageous to generate the synthesis gas at high pressure and thus avoid additional high compression costs. For this and other economic situations, coke oven gas and hydrogen from electrolysis are eliminated. This leaves hydrocarbons as the logical choice.

In the steam-hydrocarbon reforming process, steam at temperatures up to 850°C and pressures up to 30 atmospheres reacts with the desulfurized hydrocarbon feed, in the presence of a nickel catalyst, to produce H_2, CO, CO_2, CH_4, and some undecomposed steam. In a second process stage, these product gases are further reformed. Air also is added at this stage to introduce nitrogen into the gas mixture. The exit gases from this stage are further purified to provide the desired 3 parts H_3 to 1 part N_2 which is the correct empirical ratio for NH_3 synthesis. See also **Ammonia**.

T

TACHYLYTE (or Tachylite). Pure tachylite is a natural, basic black glass, which may form along the chilled contacts of dikes or sills. It also occurs as a rind on basic pillow lavas that have been suddenly chilled by plunging into water. Occasionally it forms entire flows from certain Hawaiian volcanoes.

TACONITE. A low-grade iron ore consisting essentially of a mixture of hematite and silica. It contains 25% iron. Found in the Lake Superior district and western states.

TACTICITY. The regularity of symmetry in the molecular arrangement of structure of a polymer molecule. Contrasts with random positioning of substituent groups along the polymer backbone, or random position with respect to one another of successive atoms in the backbone chain of a polymer molecule.

TAFEL REARRANGEMENT. Rearrangement of the carbon skeleton of substituted acetoacetic esters to hydrocarbons with the same number of carbon atoms by electrolytic reduction to a lead cathode in alcoholic sulfuric acid.

TALC. [CAS: 14807-96-6]. The mineral talc is a magnesium silicate corresponding to the formula $Mg_3Si_4O_{10}(OH)_2$ which occurs as foliated to fibrous masses, its monoclinic crystals being so rare as to be almost unknown. It has a perfect basal cleavage, the folia nonelastic although slightly flexible; it is sectile and very soft; hardness, 1; specific gravity, 2.5–2.8; luster, waxlike or pearly; color, white to gray or green; translucent to opaque. It has a distinctly greasy feel. Talc is a metamorphic mineral resulting from the alteration of silicates of magnesium like pyroxenes, amphiboles, olivine and similar minerals.

It is found chiefly in the metamorphic rocks, often those of a more basic type due to the alteration of the minerals above mentioned. Some localities are the Austrian Tyrol, the St. Gotthard district of Switzerland, Bavaria and Cornwall, England. In Canada, talc is found in Brome County, Quebec and Hastings County, Ontario. In the United States, well-known localities are to be found in Vermont, New Hampshire, Massachusetts, Rhode Island, New York, Pennsylvania, Maryland, and North Carolina.

A coarse grayish-green talc rock has been called soapstone or steatite and was formerly much used for stoves, sinks, electrical switchboards, etc. Talc finds use as a cosmetic, for lubricants and as a filler in paper manufacturing. Most tailor's "chalk" consists of talc. The origin of the word talc is not definitely known.

See also terms listed under **Mineralogy**.

TAMM LEVELS. Surface states; the extra electron energy levels found at crystal surfaces.

TANNIN. Substances found in many plants; generally related to one of the phenols, pyrogallol or catechol. By their action on animal skins, they cause changes that make the skins resistant to decomposition and at the same time leave them flexible and very strong, greatly improved in wearing qualities. Skins so treated are said to be tanned, and are called leather. Tanning is a very old art, having been practiced in China since long before the Christian era. It was also known to the American Indians before the arrival of the Europeans.

Tannins are found in various parts of the plant, appearing frequently in leaves, and in the cortical tissues of stems. Tannins may be found in the walls of cells or in the vacuoles; often their presence causes the cell to appear dark-colored. Many fruits, such as the persimmon, contain large amounts of tannin, especially before they are ripe. Wound tissues, and especially the hypertrophied tissues known as galls, which result from the bits of certain insects, are particularly rich in tannins. Tannins appear to be by-products of the metabolism of the plant. When present in the epidermal cells, tannins are seen as a deterrent to snails, which might injure the leaf by feeding on it, to parasitic fungi, which might otherwise enter the leaf tissue, and as a protection against desiccation, since they form substances impervious to water.

An important source of tannin is the bark of various trees, especially that of the hemlock and several species of oaks. The bark is removed from the tree in sheets approximately 4 feet long. Stripping from the tree is usually done in the spring, when the cambial cells are most active and the bark separates easily. To remove the bark, two rings are cut completely through the bark and around the tree. A longitudinal slit is made through the bark from one ring to the other. With the use of a blunt, long-handled implement, the bark is then pried loose from the tree and allowed to dry. By felling the tree, the entire trunk may be stripped of its bark in this way. The dried bark is shipped to mills, where the tannin is extracted. Tannins from these barks are used to tan leather for shoe-soles and other heavy leathers. The wood of the chestnut tree yields a tannin similarly used.

Trees of the genus *Schinopsis*, native to the southern part of South America, including southern Brazil, Bolivia and other southern countries are very important source of tannin. These trees are known by the name "quebracho," which means "ax-breaker," because of their very hard, dense, heavy, dark-red wood, which is cut with difficulty. The heartwood of the tree contains 20–27% tannin, which is obtained by cutting the wood into small chips and extracting with water. This tannin is often used in combination with tannins from other plants.

The bark of many other trees yields large amounts of tannins. Among these are the mangrove, and several species of Acacia, known as wattles, natives of Australia. Fruits also may be a source of tannin. The fruits of *Terminalia chebula*, called *myrobalans*, are an important tannin source. The tree is a native of tropical Asia. Another fruit rich in tannin is *divi-divi*, the pods of a legume, *Caesalpinia coriaria*, which is native in tropical America and the West Indies. Sumac leaves, especially those of *Rhus coriaria*, a shrub or small tree native in Mediterranean Europe, are rich in tannins. To obtain the tannin, the plants are cut down and spread out to dry. The leaves are then removed from the stems and packed into bags, which are shipped to the mills. There the leaves are first cleaned and then ground up. The tannins from this source are used in manufacturing fine leathers, like glove leathers. Leaves of other species of sumac, including the various American sumacs, also contain tannins which, however, are not so valuable and are little used.

Tannins are solids, soluble in water or alcohol, usually extracted by hot water, insoluble in ether, chloroform, carbon disulfide, benzene, soluble in alcohol-ether mixture, and in ethyl acetate, possessing a bitter astringent taste. Tannins (1) yield precipitates with gelatin, proteins (connected with the property of making leather from hides), alkaline salt solutions of many heavy metals, e.g., lead acetate, copper acetate (precipitate brown), antimonyl tartrate, concentrated dichromate solution, also by chromic acid (1% CrO_3); (2) yield dark blue or green coloration with ferric salt solutions; (3) in alkaline solution, absorb oxygen and yield dark colored solution; (4) with iodine in potassium iodide plus small proportion of ammonium hydroxide, yield red color (5) with dilute solution potassium hexacyanoferrate(II) in ammonium hydroxide, yield a red to brown coloration (care not to use excess reagent).

While tannins probably vary in composition, the type generally termed tannic acid is a pentadigalloylglucose for hydrolysis yields diagallic acid and glucose.

TANTALITE. This black mineral, (Fe, Mn)(Ta, $Nb)_2O_6$, is isomorphous with columbite and dimorphous with tapiolite. Tantalite occurs in pegmatites and is a principal ore of tantalum.

TANTALUM. [CAS: 7440-25-7]. Chemical element symbol Ta, at. no. 73, at. wt. 180.948, periodic table group 5, mp 2,996°C, bp 5,427°C, density 16.65 g/cm^3 (solid at 20°C), 17.1 (single crystal). Elemental tantalum has a body-centered cubic crystal structure. Because of high mp, it is considered a refractory metal.

Tantalum is a slightly bluish metal; ductile, malleable, and when polished resembles platinum; burns upon being heated in air; insoluble in HCl or HNO_3, but soluble in hydrofluoric acid or a mixture of hydrofluoric and HNO_3. The tough, impermeable oxide film formed on the metal when exposed to air makes tantalum the most resistant of all metals to atmospheric corrosion. Tantalum was first identified by Ekeberg as a new element in yttrium minerals in 1802 and was first obtained in pure form by Berzelius in 1820 by heating potassium tantalofluoride with potassium. There is one, naturally occurring stable isotope ^{181}Ta. ^{180}Ta also occurs naturally (isotopic abundance 0.012%), with a half-life of something greater than 10^7 years. At least nine other radioactive isotopes have been identified ^{176}Ta through ^{179}Ta and ^{182}Ta through ^{186}Ta. With exception of ^{179}Ta (half-life of about 600 days), the remaining half-lives are expressed in minutes, hours, or days. ^{182}Ta has been used as a source of gamma rays. See also **Radioactivity**. In terms of abundance, tantalum does not appear on the list of the first 36 elements that occur in the earth's crust and hence is relatively scarce. Also, tantalum does not appear on the list of the first 65 elements that are found in seawater. First ionization potential, 7.7 eV. Oxidation potential $2Ta + 5H_2O \leftarrow Ta_2O_5 + 10H^+ + 10e^-$, 0.71V. Other important physical properties of tantalum are given under **Chemical Elements**.

Tantalum is found in a number of oxide minerals, which almost invariably also contain niobium (columbium). The most important tantalum-bearing minerals are tantalite and columbite, which are variations of the same natural compound (Fe, Mn)(Ta, $Nb)_2O_6$. Much of the tantalum concentrates has been obtained as a byproduct from tin mining; in recent years, tin slags, which are a byproduct of the smelting of cassiterite ores, such as those found in the Republic of Congo. Nigeria, Portugal, Malaya, and Thailand have been an important raw material source for tantalum.

The first successful industrial process used to extract tantalum and niobium from the tantalite-columbite-containing minerals employed alkali fusion to decompose the ore, acid treatment to remove most of the impurities, and the historic Marignac fractional-crystallization method to separate the tantalum from the niobium and to purify the resulting K_2TaF_7. Most tantalum production now employs recovery of the tantalum and niobium values by dissolution of the ore or ore concentrate in hydrofluoric acid. Then the dissolved tantalum and niobium values are selectively stripped from the appropriately acidified aqueous solution and separated from each other in a liquid-liquid extraction process using methyl isobutyl ketone (MIBK) or other suitable organic solvent. The resulting purified tantalum-bearing solution is generally treated with potassium fluoride or hydroxide to recover the tantalum in the form of potassium tantalum fluoride, K_2TaF_7, or with ammonium hydroxide to precipitate tantalum hydroxide, which is subsequently calcined to obtain tantalum pentoxide, Ta_2O_5. Tantalum metal is generally obtained by sodium reduction of K_2TaF_7, although electrolysis of K_2TaF_7 and carbon reduction of Ta_2O_5 in an electric furnace have also been used. Tantalum metal can absorb large volumes of hydrogen during heating in a hydrogen-bearing atmosphere at an intermediate temperature range (450–700°C). The hydrogen is readily removed by heating in vacuum at higher temperatures.

Uses

Tantalum is used widely, although in small quantities in the electronics industry in electrolytic capacitors, emitters, and getters. The corrosion resistance of tantalum has been compared with that of glass. Additionally, the metal has a high heat-transfer coefficient and is easy to fabricate. Consequently, it finds use in equipment that must resist strong corrosive attack, as in the manufacture of HCl, hydrogen peroxide, in chromium plating baths, in bromine heaters and stills, and in the preparation of corrosive fine chemicals, such as ethyl bromide. The metal also has been used in resistance heaters in very high-temperature furnaces and for some nuclear reactor parts.

Alloys

Tantalum is added to nickel and nickel-cobalt superalloys for gas-turbine and jet-engine parts. Several surgical applications for tantalum have developed because of the inertness of the metal to body fluids and the tolerance of the body for the metal. Tantalum may be placed in the skull or other body parts without rejection. Strips and screws made of tantalum are used for holding broken pieces of bone and tantalum wire mesh is used for surgical staples, braid for sutures, and reinforcements. Tantalum-base alloys are used for aerospace structures and space power systems, principally because of the high-temperature stability and strength of these alloys. They operate satisfactorily at temperatures in excess of 1,600°C. Tantalum alloys are used in heat exchangers. See Fig. 1. Small additions of zirconium to tantalum increases its tensile strength at normal temperatures and up to approximately 1,200°C. Also, when added in amounts of about 5%, hafnium, molybdenum, rhenium, tungsten, and vanadium also increase the strength of tantalum. The tensile strength of ternary alloys of tantalum (Ta with 30% Nb and 5% Zr of V) at room temperature is about 3X that of tantalum alone. A tantalum-tungsten alloy is used for fabricating springs for high temperature and high vacuum applications.

The trend in the chemical industry is to use increasingly high processing temperatures and pressures, requiring stronger materials with better corrosion resistance. With these objectives in mind, researchers have been studying the influence of the alloying elements tungsten, molybdenum, niobium (columbium), hafnium, zirconium, and rhenium on both the mechanical properties and corrosion behavior of pure tantalum. They have found that additions of only 1% to 3% molybdenum to tantalum, for example, has a marked effect in decreasing the susceptibility of pure tantalum to hydrogen embrittlement in severely corrosive conditions. Not only is the corrosion rate of tantalum decreased, but mechanical properties, such as strength and room temperature workability, are also improved.

Tantalum-tungsten alloys have been successfully developed, which exhibit at least four key advantages: (1) tungsten causes a considerable solid solution hardening (SSH) effect in tantalum; (2) tungsten shows almost no evaporation during electron beam melting; (3) tungsten is less costly than tantalum; and (4) the corrosion rate of tantalum is but slightly influenced by the addition of tungsten up to about 10% (wt).

Tantalum-hafnium and tantalum-zirconium alloys are less suitable for aggressive acid environments. Compared with tantalum-tungsten alloys, tantalum rhenium alloys are superior in corrosion resistance and to hydrogen embrittlement, but the major disadvantage is the high cost of rhenium.

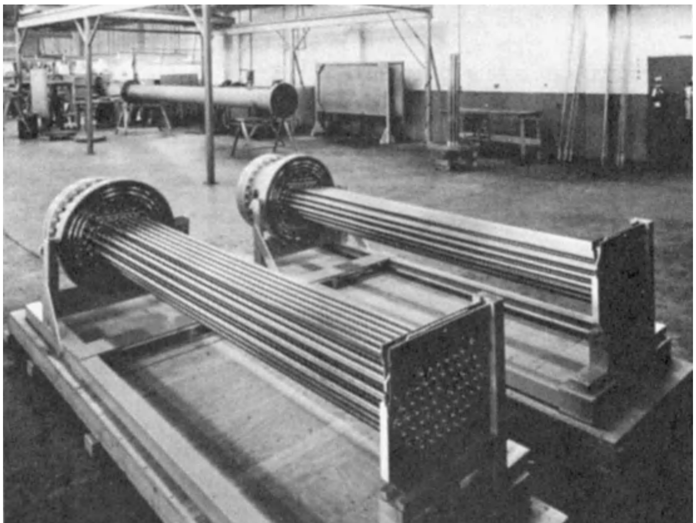

Fig. 1. High-heat-transfer bayonet-style exchangers employing tantalum alloy tubes. Each exchanger uses 104 tubes. (*Fansteel*)

TABLE 1. REPRESENTATIVE PROPERTIES OF TANTALUM ALLOYS

Alloy additions (Weight, %)	Forms commercially available	Code name	Typical high-temperature strength: Temperature, °C	Tensile, Mpa	Temperature, °C	10-h rupture, Mpa

(*After Advanced Materials & Processes*).

Some of the properties of tantalum and its alloys are given in Table 1.

Chemistry and Compounds

As might be expected from its 5d 36s 2 electron configuration, tantalum forms pentavalent compounds. In fact, they constitute the great majority of tantalum compounds, although the valences 2, 3, and 4 are known. However, the existence of the Ta^{5+} ion is very brief, since it readily coordinates with H_2O, OH^-, and other anions or molecules. Tantalum is extremely resistant to chemical action, not being attacked by acids other than hydrofluoric acid, and by alkalies only upon fusion. Even fluorine and oxygen react only on heating.

Tantalum pentoxide, formed by heating the metal with oxygen, reacts with hydrofluoric acid, alkali bisulfates or alkali hydroxides, forming tantalates with the latter. It reacts with a number of halogen compounds to give tantalum pentafluoride, pentachloride and pentabromide, TaF_5, $TaCl_5$, and $TaBr_5$. (Carbon tetrachloride is often used in this preparation of $TaCl_5$.) These compounds readily undergo hydrolysis, and may form oxyhalides, such as TaO_2F and $TaOBr_3$. They may be reduced, but with difficulty, $TaCl_5$ when heated with aluminum yielding the tetrachloride, $TaCl_4$. The trihalides, $TaCl_3$ and $TaBr_3$ have also been prepared. Tantalum(V) fluoride combines with other fluorides, notably the alkali metal fluorides, to yield complexes, such as K_2TaF_7 and Na_3TaF_8.

Other complexes of tantalum(V) are formed with oxygen-function compounds, such as o-dihydroxybenzene and acetylacetone.

In addition to Ta_2O_5, another oxide is known, TaO_2, which may be formed by active-metal reduction (as is the tetrachloride), except that the pentoxide is heated with magnesium rather than aluminum. It forms with alkali metals the metatantalates, $MTaO_3$, the orthotantalates, M_3TaO_4, and pyrotantalates, $M_4Ta_2O_7$, as well as such polytantalates as $M_8Ta_6O_{19}$, the latter requiring fusion with the alkali hydroxides.

The only known sulfide, which is produced by heating with carbon disulfide, is TaS_2, but at least two nitrides are known, TaN and Ta_3N_5, the latter being unstable.

The organometallic compounds of tantalum all involve oxygen bonding, with the exception of a dicyclopentadienyl compound, $(C_5H_5)_2TaBr_3$. The others are alkoxy compounds, such as $(C_2H_5O)_3TaCl_2$, $Ta(OC_2H_5)_5$, $Ta(OCH(C_2H_5)CH_3)_5$, etc., with the exception of bis(fluorosulfonyloxy) trichlorotantalane, $Cl_3Ta(OS(O_2)F)_2$.

A major portion of this article was furnished by M. SCHUSSLER FANSTEEL North Chicago, Illinois

TAR ACID. Any mixture of phenols present in tars or tar distillates and extractable by caustic soda solutions. Usually refers to tar acids from coal tar and includes phenol, cresols, and xylenols. When applied to the products from other tars it should be qualified by the appropriate prefix, e.g., wood tar acid, lignite tar acid, etc. See also **Coal Tar and Derivatives**.

TARNISH. A reaction that occurs readily at room temperature between metallic silver and sulfur in any form. The well-known black film that appears on the silverware results from reaction between atmospheric sulfur dioxide and metallic silver, forming silver sulfide. It is easily removable with a cleaning compound and is not a true form of corrosion. Plating with a mixture of silver and indium will increase tarnish resistance. Gold will also tarnish in the presence of a high concentration of sulfur in the environment.

TAR SANDS. Also called *bituminous sands* and *oil sands*, tar sands represent a vast potential of petroleum like energy reserves and a reservoir of materials for the preparation of syncrudes. In 1988, the processing of tar sands is steadily approaching a state of economic viability. Although there are major technological problems remaining in the recovery and processing of tar sands into practical fuels, the overriding factor affecting progress in this field is a combination of economics and technology.

The heavy, viscous petroleum substances impregnating the tar sands are called *asphaltic oils*. Other names used to describe these oils include *maltha, brea*, and *chapapote*. Asphaltic petroleums are most commonly confused with, but are *not* related to *asphaltites* (gilsonite, glance pitch, and grahamite); the *asphaltic pyrobitumens* (elaterite, wurtzilite, albertite, and impsonite); the native *mineral wax* (ozokerite); and the *pyrogenous distillates* of bituminous substances (tar and pitch).

Tar sands are composed of a mixture of 84–88% sand and mineral-rich clays, 4% water, and 8–12% bitumen. Bitumen is a dense, sticky, semisolid that is about 83% carbon. The substance does not flow at room temperature and is heavier than water. At higher temperatures, it flows freely and floats on water. Characteristics of tar sands important to mining, recovery, and processing include grain size, composition, sortability, porosity, permeability, and microscopic habitat.

Tar Sand Resources

The presence of tar sands in North America was noted by American Indians several centuries ago. Pitch recovered from surface deposits was used for waterproofing canoes. It is reported that Columbus observed asphalt from Pitch Lake in Trinidad and used the material for repairing his ships on his third voyage to the West Indies in 1498. The same bitumen deposit was reported by Sir Walter Raleigh in 1595. For several centuries the material was used for repairing vessels.

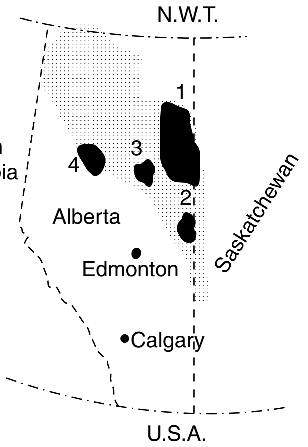

Fig. 1. Location of major tar (oil) sand deposits in Alberta, Canada: (1) Athabasca, (2) Cold Lake, (3) Wabasca, and (4) Peace River, N.W.T. (Northwest Territories)

Fig. 2. General view of upgrading plant for processing bitumen mined from Athabasca deposit. In the foreground is the sulfur stockpile; in the background is a tailings pond. Right background shows the extraction plant; left is the coke pile. (*Alberta Government Photographic Service*)

In 1962, reports were received of tar sands in the Bjorne Formation of Triassic age on Melville Island in the Canadian Arctic Archipelago near the southern margin of the Sverdrup sedimentary basin. Subsequent investigations of these deposits by officers of the Geological Survey of Canada revealed them to be a seepage derived from the oxidation and polymerization of 19–31° API gravity oil, with a total in-place reserves of only 30 million barrels. The largest find of tar sands in Canada (and possibly in the world) was located in the subsurface of northern Alberta in the valley of the lower Athabasca River, along a distance of 160 kilometers (100 miles). This is now known as the Athabasca deposit. As indicated by Mossop (1980), McMurray Formation deposition began in the Athabasca region in Early Cretaceous time. The surface on which the initial sediments were laid down was an exposed landscape of Devonian limestone. It is envisioned that, during the McMurray period, the region underwent gradual subsidence, with the Boreal Sea[1] slowly transgressing across it from the north. The McMurray sand deposition stopped when the sea eventually transgressed the entire area, giving subsequent rise to deposition of Clearwater Formation marine shales. Not all geologists are agreed upon the details of the formation and possible later biodegradation of tar sand deposits. Geographically close to the Athabasca deposit are the Cold Lake, Wabasca, and Peace River deposits. Underlying these Cretaceous tar sands are Devonian carbonate rocks (limestone and dolomite) impregnated with bitumen of essentially the same composition as the bitumen in the Cretaceous sands. See Fig. 1.

[1] Boreal is a term that pertains to the north, or to things located in northern regions. The Boreal region is characterized by tundra and taiga—a climatic zone having a definite winter that experiences snow and a short summer that is generally hot, characterized by a large annual range of temperature. This region includes parts of North America, central Europe, and Asia, generally between latitudes 60°N and 40°N.

Along with other alternative sources of energy during the energy crisis of the 1970s, considerable attention was devoted to the exploitation of tar sands. Once, it was predicted that deposits in Canada could yield a light synthetic crude oil to the extent of a million barrels per day, or about one-third of Canada's petroleum requirements. Later, when serious environmental concern over fossil fuels was indicated, research turned essentially elsewhere. It was estimated in the late 1970s that tar sands reserves in the United States, mainly in Utah, would have the petroleum equivalent of 90 billion barrels.

It is interesting to note that tar sands worldwide contain the largest accumulations of liquid hydrocarbons in the earth's crust.

The seriousness of the Canadian tar sands effort is demonstrated by a view of a plant in Alberta as of about 1980. See Fig. 2.

TARTARIC ACID. [CAS: 87-69-4]. $(CHOHCO_2H)_2$, formula weight 150.09, white crystalline solid with four physical isomers, three of which are optically active: (1) dextro- and (2) levotartaric acid, both with same mp 168–170°C and sp gr 1.760, (3) racemic acid (dextrolevo), mp 205–206°C, sp gr 1.697, and (4) mesotartaric acid (inactive), mp 159–160°C, sp gr 1.737. Racemic acid crystallizes with one molecule of H_2O. All forms decompose before reaching the boiling point at atmospheric pressure. All forms are soluble in H_2O, slightly soluble in alcohol, and essentially insoluble in ether. Tartaric acid is a primary example of optical isomerism and one of the earliest compounds studied in this regard. Tartaric acid is a dibasic acid with two series of salts and esters.

Tartrates (like citrates) in solution change silver of ammonio-silver nitrate into metallic silver. Potassium hydrogen tartrate and calcium tartrate, on account of their solubility characteristics, are of importance in the separation and recovery of tartaric acid. The former salt is readily converted into the latter, and the resulting calcium tartrate plus dilute sulfuric acid yields tartaric acid plus calcium sulfate, and the latter may be separated by filtration. Tartaric acid may be obtained by evaporation of the filtrate. Ester: Diethyl tartrate $COOC_2H_5(CHOH)_2COOC_2H_5$, melting point 17°C, boiling point 280°C. Tartaric acid may be obtained (1) from some natural products, e.g., in the juice of grapes and acid fruits, often in conjunction with citric or malic acid; potassium hydrogen tartrate, "argol," in the residue of wine vats, (2) by synthesis.

Tartaric acid is used: (1) in baking powders as potassium hydrogen tartrate ("cream of tartar") with sodium bicarbonate; (2) in medicine, e.g., potassium antimonyl tartrate ("Tartar emetic"); (3) in effervescent medicinal salts; (4) in blue printing as ferric tartrate; and (5) in silvering mirrors—ammonio-silver nitrate yielding a smooth deposit of silver. Sodium potassium tartrate ("Rochelle salt," $NaKC_4H_4O_6 \cdot 4H_2O$) is used in medicine, and in the preparation of Fehling's solution, which is an alkaline cupric solution made by mixing copper sulfate solution, sodium potassium tartrate solution and sodium hydroxide solution, and is used as an oxidizing reagent in the case of many organic compounds, such as glucose and reducing sugars, and aldehydes, with which cuprous oxide, red to yellow precipitate, is formed.

See also **Isomerism**.

TAUBE, HENRY (1915–). A Canadian-born chemist who won the Nobel prize for Chemistry in 1983 for his pioneering work in inorganic chemistry and the study of electron-transfer reactions, particularly of metal complexes. Known as an outstanding teacher, he is admired and respected by students and colleagues for his work at Stanford University.

TAU CYCLE. See **Carbohydrates**.

TAU PARTICLE. Discovered in 1975, the tau particle is a lepton with a mass of 1.8 GeV, almost twice that of the proton. Like other leptons, the tau particle is considered as pointlike. See also **Particles (Subatomic)**.

TCA CYCLE. (tricarboxylic acid cycle; Krebs cycle or citric acid cycle). A series of enzymatic reactions occurring in living cells of aerobic

organisms, the net result of which is the conversion of pyruvic acid, formed by anaerobic metabolism of carbohydrates, into carbon dioxide and water. The metabolic intermediates are degraded by combination of decarboxylation and dehydrogenation. It is the major terminal pathway of oxidation in animal, bacterial, and plant cells. Recent research indicates that the TCA cycle may have predated life on earth and may have provided the pathway for formation of amino acids.

TECHNETIUM. [CAS: 7440-26-8]. Chemical element symbol Tc, at. no. 43, at. wt. 98.906, periodic table group 7, mp 2172°C, bp 4877°C, does not occur in nature. The present location of technetium in the periodic table was vacant for many years, during which time several claims to having found the element were made, but never confirmed. One such claimant termed the element masurium. Technetium has been detected in certain stars and this discovery must be resolved with current theories of stellar evolution and element synthesis.

^{97}Tc, the first isotope to be isolated, was extracted by Perrier and Segré in 1937 from molybdenum which had been bombarded with deuterons in the Berkeley cyclotron. The reaction was $^{96}\mathrm{Mo}(d,n)^{97}\mathrm{Tc}$. The isotope with the longest half-life, ^{99}Tc (half-life = 2.12×10^5 years), is found in relatively large amounts among the fission products of uranium. It is also produced by neutron irradiation of ^{98}Mo, by the reaction

$$^{98}\mathrm{Mo}(n,\gamma)^{99}\mathrm{Mo}(\beta-\mathrm{decay})^{99m}\mathrm{Tc}(\text{isomeric transition})^{99}\mathrm{Tc}$$

Significant quantities have been isolated and considerably larger quantities could be made available if applications for it were developed. A U.S. government-owned invention available for licensing concerns a method for recovering technetium from nuclear fuel reprocessing waste solutions. ^{99}Tc has found some application in diagnostic medicine. Ingested soluble technetium compounds tend to concentrate in the liver and are valuable in labeling and in radiological examination of that organ, and this was the basis of the early medical uses. However, the ideal nuclear properties of ^{99m}Tc have led to expanded usage in medical diagnostics. By technetium labeling of suitable compounds (or blood serum components), diseases involving the circulatory system and organs other than the liver can be diagnosed.

In all, sixteen isotopes of technetium have been reported of mass numbers 92–105, 107, and 108.

Superconductivity has been observed in technetium metal and in alloys based on technetium with additions of Pd, Os, Rh, Ru, Sn, V, Ti, Re, W, or C.

A study of the chemistry of technetium shows it to have, as expected, properties intermediate between those of its homologues manganese and rhenium, the resemblance to the latter being perhaps greater than to the former. Like rhenium, technetium apparently exists in (IV), (VI), and (VII) oxidation states. Pure technetium metal has been prepared by passing hydrogen gas at 1,000°C over the sulfide obtained by precipitation with H_2S from HCl solution. The metal has been shown to have the same crystal structure as rhenium and the adjacent elements osmium and ruthenium. Among its compounds are the ditechnetium heptasulfide, Te_2S_7, readily precipitated by H_2S from oxidized solutions, the corresponding oxide, Tc_2O_7 produced directly from the elements at higher temperatures, which reacts with NH_3 to form ammonium pertechnate, NH_4TcO_4, and the hexachloro complex ion, $TcCl_6{}^{2-}$, which like the corresponding rhenium ion, has a magnetic moment corresponding to three unpaired electron spins.

In 1991, cardiologists (University of California, Los Angeles) reported the use of a new combination of mixtures for yielding images of healthy and damaged areas of the heart. This enables physicians to assess the effectiveness of clot-busting drugs and other cardiac therapies. Use of the technique as a preventive measure for determining persons at risk of sudden blood-flow blockages and thus sudden heart attacks also has been suggested. The product (DuPont-Merck) is called *technetium-99 m sestamibi*. Technetium-99 m is a tracer, and sestamibi is an effective "heart-seeking" compound. This technique is superior to use of the thallium radioisotope because of the requirements of thallium to process images within 30 minutes of injection. Technetium is not that time-sensitive.

TEKTITE. A small (usually walnut-size), rounded, pitted, jet-black to olive-greenish or yellowish body of silicate glass of nonvolcanic origin, found usually in groups in several widely separated areas of the earth's surface and apparently bearing no relation to the associated geologic formations. Most tektites have uniformly high silica (68–82%) and very low water contents (average, 0.005%). Their composition is unlike that of obsidian and more like that of shale. They have various shapes, strongly suggesting modeling by aerodynamic forces and they average a few grams in weight. The largest found weighs 3.2 kilograms. Some authorities believe that tektites are of extraterrestrial origin, or alternatively the product of large hypervelocity meteorite impacts on terrestrial rocks. The term was proposed by Suess in 1900 who believed they were meteorites which at one time had undergone melting.

TELLURIUM. [CAS: 13494-80-9]. Chemical element, symbol Te, at. no. 52, at. wt. 127.60, periodic table group 6, mp 450°C, bp 690°C, density 6.24 g/cm^3 (crystalline form at 25°C), 6.00 (amorphous form at 25°C). Elemental tellurium has a hexagonal crystal structure with trigonal symmetry. Tellurium is a silver-white brittle semi-metal, stable in air, and in boiling H_2O, insoluble in HCl, but dissolved by HNO_3 or aqua regia to form telluric acid. The element is dissolved by NaOH solution and combines with chlorine upon heating to form tellurium tetrachloride.

In observing a peculiar phase in gold ores of the Transylvania region, Franz Müller von Reichenstein first identified the element in 1782. There are several natural occurring isotopes ^{120}Te, ^{122}Te through ^{126}Te, ^{128}Te, and ^{130}Te. Nine radioactive isotopes have been identified ^{118}Te, ^{119}Te, ^{121}Te, ^{123}Te, ^{127}Te, ^{129}Te, and ^{131}Te through ^{133}Te. With exception of ^{123}Te which has a half-life something greater than 10^{13} years, all of the other radioactive isotopes have half-lives measurable in terms of minutes, hours, or days. In terms of abundance, tellurium does not appear on the list of the first 36 elements that occur in the Earth's crust and hence is relatively scarce. Terrestrial abundance is estimated on the order of 0.002 ppm. Tellurium is found in seawater to the estimated extent of about 95 pounds per cubic mile of seawater. First ionization potential 9.01 eV; second, 18.6 eV; third, 30.5 eV; fourth 37.7 eV; fifth, 59.95 eV. Oxidation potentials $H_2Te(aq) \longrightarrow Te + 2H^+ + 2e^-$, 0.69 V; $Te + 2H_2O \longrightarrow ReO_2(s) + 4H^+ + 4e^-$, −0.529 V; $TeO_2(s) + 4H_2O \longrightarrow H_6TeO_6(s) + 2H^+ + 2e^-$, −1.02 V; $Te^{2-} \longrightarrow Te + 2e^-$, 0.92 V; $Te + 6OH^- \longrightarrow TeO_3{}^{2-} + 3H_2O + 4e^-$, 0.02 V; $Te \longrightarrow Te^{4+} + 4e^-$, −0.564 V. Electronic configuration $1s^22s^22p^63s^2ep^63d^{10} - 4s^24p^64d^{10}5s^25p^4$. Other important physical properties of tellurium are given under **Chemical Elements**.

Tellurium occurs chiefly as telluride in gold, silver, copper, lead, and nickel ores in Colorado, California, Ontario, Mexico, and Peru, and infrequently as free tellurium and tellurite (tellurium dioxide, TeO_2). The anode mud from copper and lead refineries, or the flue dust from roasting telluride gold ores is treated by fusion with sodium nitrate and carbonate and the melt extracted with water. The resulting solution is acidified carefully with H_2SO_4, whereupon tellurium dioxide is precipitated, and the dioxide reduced to free tellurium by heating with carbon.

Uses

On the scale of most other commercial metals, the production of elemental tellurium is relatively limited—approximately $\frac{1}{2}$ million pounds annually. Commercial tellurium is marketed at a purity of about 99.7%, although much purer forms are obtainable—up to 99.999%. The application of tellurium and tellurium compounds as catalysts is expanding. Small quantities are used in various electronic components, including solar cells, infrared detectors, emitters, and thermoelectric generators. Tellurium also is sometimes used as a dopant for semiconductor

devices. The metal has been used in primer fuses for explosives. The main applications have been in metallurgy. Small additions of tellurium improve the machinability of low-carbon steels, stainless steels, and copper. The metal stabilizes the carbide in cast irons. Tellurium also helps to control pinhole porosity in steel castings. The very small addition (0.05%) of tellurium to lead improves a number of the physical properties of lead sheet, foil, and other shapes. To some extent, tellurium has been used as a curing agent and accelerator in rubber compounds.

Chemistry and Compounds

Tellurium occurs in the same periodic classification as sulfur, selenium, and polonium. Tellurium, unlike sulfur and selenium, has only two allotropic forms. Due to its $5s^2 5p^4$ electron configuration, tellurium, like sulfur and selenium, forms many divalent compounds with covalent bonds and two lone pairs, and d-hybridization is quite common, to form compounds with tellurium oxidation states of +4 and +6.

Tellurium dioxide, [CAS: 7446-07-3], TeO_2, made directly from the element or by heating tellurous acid, H_2TeO_3, is a solid, subliming at 450°C, insoluble in H_2O, which dissolves in acids and alkalis, exemplifying the increasing metallic character with atomic weight of the main group 6 elements. Tellurium dioxide accepts a proton from strong acids to form the ion $TeOOH^+$. Dehydration of telluric acid at 400°C produces TeO_3, tellurium trioxide. It is not nearly as reactive as sulfur trioxide and selenium trioxide, but reacts with alkali hydroxides to form tellurates.

Tellurous acid, H_2TeO_3, can exist only in very dilute aqueous solutions (due to insolubility of TeO_2). It is a weak acid (ionization constants 2×10^{-3} and 2×10^{-8}). The salts of tellurous acid, the tellurites, may often be formed by reaction of TeO_2 with metal salts. Telluric acid, H_6TeO_6, is prepared by oxidation of tellurium with strong oxidizing agents, such as 30% hydrogen peroxide or boiling HNO_3 and catalyst. Various values of the ionization constants of telluric acid have been reported, on the order of 10^{-7} and 10^{-11}, but the best values would appear to be $pK_{A1} = 7.7$, $pK_{A2} = 11.0$, $pK_{A3} = 14.5$. Telluric acid is a quite strong oxidizing agent, forming halogens from hydrohalides in solution (except hydrogen fluoride). The alkali metal tellurates have the composition $M_2H_4TeO_6$, although metal tellurates with all H's replaced exist, such as Hg_3TeO_6 and Zn_3TeO_6.

Hydrogen telluride is a stronger acid than H_2S (ionization constants 2.27×10^{-3} and 10^{-11} (?) at 18°C) and is less readily obtained from tellurides than hydrogen sulfide from sulfides. Aluminum telluride, Al_2Te_3, requires heating with H_2O or dilute acids. In general the metal tellurides are prepared by direct combination of the elements. Those of the transition metals and the zinc, gallium and germanium families exhibit many instances of both well defined compounds and non-daltonide compositions, as well as substitutional solid solutions. Also six intermediate phases are found in the palladium-tellurium system, Pd_4Te, Pd_3Te, $Pd_{2.5}Te$, Pd_2Te, PdTe, and $PdTe_2$.

Tellurium hexafluoride, [CAS: 7783-80-4], TeF_6, the only clearly defined tellurium hexahalide, is formed directly from the elements at 150°C, while at 0°C the product is mainly the decafluoride, Te_2F_{10}. TeF_6 is a relatively weak Lewis acid, forming complexes with pyridine and other nitrogen bases. Tellurium tetrahalides of all four halogens exist, the TeF_4 formed from $TeCl_2$ and fluorine, the $TeCl_4$ from $TeCl_2$ and chlorine, the $TeBr_4$ from bromotrifluoromethane, CF_3Br, and molten tellurium, and the TeI_4 directly from the elements. Tellurium dichloride, $TeCl_2$, is prepared by passing dichlorodifluoromethane, CF_2Cl_2, over molten tellurium. $TeCl_2$ is quite reactive, disproportionating to tellurium and $TeCl_4$, and useful in preparing other tellurium compounds. $TeBr_2$ is obtained by distillation of the mixture of tellurium and $TeBr_4$ obtained in the reaction between bromotrifluoromethane and tellurium. The tetrahalides of tellurium form many addition compounds with other halides.

Organotellurium compounds corresponding generally to those of sulfur and selenium are known. Although carbon ditelluride has not been prepared, COTe and CSTe have been.

Toxicity

Tellurium and compounds are toxic. Acceptable concentration limit for an 8-hour daily exposure to dust and fumes in air is 0.1 milligrams of tellurium per cubic meter of air. Even exposure at this level may cause what is termed "garlic breath." Proper ventilation, appropriate hygienic practices, and good housekeeping should be observed in handling tellurium. Although elemental tellurium causes no apparent problems in contact handling, skin contact with soluble tellurium compounds must be avoided.

TELOMERIZATION REACTIONS. In telomerization reactions, a polymerizable unsaturated compound (the taxogen) is reacted under polymerization conditions in the presence of radical-forming catalysts or promoters with a so-called telogen. During the reaction, the telogen is split into radicals that attach to the ends of the polymerizing taxogen and in some instances add on to the double bond of the taxogen and thereby form chains whose therminal groups are formed of the radicals from the telogen.

Organic compounds containing an olefinic double bond, such as thylene, propylene, hexene, octene, or styrene, are normally employed as taxogens. Many different types of compounds can be employed as telogens, for example, halogenated hydrocarbons, such as chloroform or carbon tetrachloride, halogen derivatives of cyanogen, such as cyanogen chloride, aldehydes, alcohols, and the like.

Radical-forming catalysts, such as organic peroxides, hydrogen peroxide, aliphatic azo compounds of the type of azoisobutyric acid nitrile, and redox systems are employed for telomerization reactions.

Telomerization reactions are as a rule carried out at an elevated temperature up to 250 degrees. When volatile reactants are used, the reaction is carried out under elevated pressures, e.g., between 20 and 1000 atmospheres.

TEMPERATURE. The thermal state of a body, considered, with reference to its ability to communicate heat to other bodies (J. C. Maxwell). There is a distinction between temperature and heat, as is evidenced by Helmholtz's definition of heat, (energy that is transferred from one body to another by a thermal process), whereby a thermal process is meant radiation, conduction, and/or convection.

Temperature is measured by such instruments as thermometers, pyrometers, thermocouples, etc., and by scales such as centigrade (Celsius), Fahrenheit, Rankine, Reaumur, and absolute (Kelvin).

See also **Absolute Temperature**; **Thermodynamics**; and **Temperature Scales and Standards**.

TEMPERATURE SCALES AND STANDARDS. That property of systems which determines whether they are in thermodynamic equilibrium. Two systems are in equilibrium when their temperatures (measured on the same temperature scale) are equal. The existence of the property defined as temperature is a consequence of the zeroth law of thermodynamics. The zeroth law of thermodynamics leads to the conclusion that in the case of all systems there exist functions of their independent properties x_i such that at equilibrium

$$\phi_a(x_{ia}) = \phi_b(x_{ib}) = \theta \tag{1}$$

where subscripts a and b refer to two systems a and b each described by n_a properties x_{ia}, and n_b properties x_{ib}, respectively. The hypersurface

$$\theta = \phi(x_i) = \text{constant}$$

is called an *isotherm*, and the pairs of hypersurfaces, Equation (1), at equilibrium are called *corresponding isotherms*.

In order to establish a *temperature scale* it is necessary to assign numerical values θ to these corresponding isotherms in an arbitrary manner, subject only to the condition that the resulting function shall be single-valued. A temperature scale is established by taking the following steps:

1. An arbitrary system is chosen (*thermometer*).
2. It is agreed to maintain $n-1$ properties of the system constant, and to use the nth property (*thermometric property* $x_n = X$) as a measure of temperature θ.
3. A single-valued *thermometric function* is assumed. Usually the function is simple, for example

$$\theta = aX \quad (2)$$

or

$$\theta = AX + B. \quad (3)$$

The function usually contains one or several constants (a, A, B, etc.).
4. The values of the constants in the thermometric function are determined with reference to fixed thermometric points whose temperatures are arbitrarily assumed. The *fixed thermometric points* most frequently employed are: the *ice point, steam point* and *triple point* of water.

It is not surprising that there exist many different scales of temperature, so-called *empirical temperature scales*, because of the large amount of arbitrariness inherent in the choice.

A *Centigrade* (or *Celsius*) *temperature scale* is obtained by choosing the thermometric function, Equation (3), and assigning the following arbitrary values of temperature, θ, to the ice point (θ_i) and steam point (θ_s) respectively

$$\theta_i = 0°\text{C}.$$

$$\theta_s = 100°\text{C}.$$

Hence on a Centigrade scale

$$\theta = 100\frac{X - X_i}{X_s - X_i} \quad (4)$$

(X_s measured at θ_s, X_i measured at θ_i).

A Fahrenheit temperature scale is obtained by using Equation (3) but with

$$\theta_i = 32°\text{F}$$

$$\theta_s = 212°\text{F}.$$

Hence

$$\theta = 32° + 180°\frac{X - X_i}{X_s - X_i}. \quad (5)$$

An *absolute scale* is obtained by choosing Equation (2). Depending on the value assigned to a, we obtain the *Kelvin* or *Rankine scale*. The *Kelvin absolute temperature scale* assigns to the triple point of water the value

$$\theta_3 = 273.16°\text{K} \quad (6)$$

which thus becomes a *universal constant of physics*. Hence for the Kelvin scale

$$\theta = 273.16\frac{X}{X_3} \quad (7)$$

where X_3 is measured at θ_3. For the *Rankine absolute temperature* scale we assume

$$\theta_3 = 273.16 \times 1.8°\text{R} = 491.69°\text{R}. \quad (8)$$

It is clear that by definition

$$1°\text{K} = 1.8°\text{R}, \quad (9)$$

and that on the Rankine scale

$$\theta = 491.69°\frac{X}{X_3}. \quad (10)$$

Different empirical temperature scales will naturally differ from each other except at the respective fixed thermometric points. Even different scales of the same type (say different Centigrade scales) will differ at all temperatures, except the steam point and ice point, depending on the fortuitous properties of the system chosen as a thermometer. It is, therefore, necessary to remove these differences and to obtain a more universal scale. This has been achieved in two ways. The practical way of achieving uniformity is to lay down detailed rules concerning the thermometer (actually different thermometers depending on the range of temperatures to be measured). Such rules have been agreed on internationally and constitute the *international temperature scale*. Another way is to derive a universal scale from the principles of thermodynamics. The latter is called a *thermodynamic temperature scale*. Some authors refer to it as the *absolute temperature scale* which may be a source of confusion with the Kelvin and Rankine scales described earlier.

The *thermodynamic temperature scale* T is defined by the second law of thermodynamics. It can be shown that the *thermodynamic temperature scale* is identical with the *perfect-gas temperature scale* defined as follows:

1. The system is a gas thermometer (filled with a *real* gas).
2. The thermometric property is the product pV *extrapolated to* zero pressure, i.e.,

$$r = \lim_{p \to 0}(pV) \quad (11)$$

Hence the *thermodynamic Kelvin scale* is given by

$$T = 273.16\frac{r}{r_3}(\text{K abs.}) \quad (12)$$

the *thermodynamic Centigrade scale* is given by

$$t - 100\frac{r - r_i}{r_s - r_i}(\text{degrees C}), \quad (13)$$

the *thermodynamic Rankine scale* is given by

$$T = 491.69\frac{r}{r_3}(\text{degrees R abs.}), \quad (14)$$

and the *thermodynamic Fahrenheit scale* is given by

$$t = 32 + 180\frac{r - r_i}{r_s - r_i}(\text{degrees F}). \quad (15)$$

The zeros on the Kelvin and Rankine scales coincide and are termed the *absolute zero of temperature*. The absolute zero of temperature cannot be achieved by any finite process, as stated in the third law of thermodynamics.

The relation between the Centigrade and Kelvin thermodynamic scales is determined by

$$T_i = 273.16°\text{K} = 0°\text{C} \quad (16)$$

and that between the Fahrenheit and Rankine scales is determined by

$$T_i = 491.69°\text{R} = 32°\text{F}. \quad (17)$$

Hence the absolute zero of temperature is at

$$-273.16°\text{C or } -459.69°\text{F}. \quad (18)$$

The Comité Consultative of the International Committee of Weights and Measures selected 273.16°K as the value for the triple point of water. This set the ice-point at 273.15°K.

The relation between the *international temperature scale* and the thermodynamic temperature scale must be determined empirically with the aid of careful measurements involving gas thermometers.

See also **Units and Standards**.

TEMPERATURE TRANSFER STANDARD. A device for the transfer of a temperature scale from one standardizing laboratory to another. One form consists of a sample of a purified material, the freezing point of which (when realized by a prescribed technique) is reproducible within narrow limits. Materials commonly employed are metals, such as zinc and tin, and organic compounds, such as benzoic acid, phenol, naphthalene, and phthalic anhydride. Another form is a tungsten ribbon-filament lamp, characterized by a stable lamp current-brightness temperature relation. This device is particularly useful for temperatures above 1,050°C.

TENACITY. Strength per unit weight of a fiber or filament, expressed as g/denier. It is the rupture load divided by the linear density of the fiber.

See also **Tensile Strength**.

TENORITE. A mineral oxide and ore of copper, CuO. Crystallizes in the monoclinic system. Hardness, 3.5; specific gravity, 6.45; color, gray to black with metallic luster. Named after M. Tenore (1780–1861), Naples.

TENSILE STRENGTH. The rupture strength (stress-strain product at break) per unit area of a material subjected to a specified dynamic load; it

is usually expressed in pounds per square inch (psi). This definition applies to elastomeric materials and to certain metals.

See also **Tenacity**.

TENSIOMETER. An apparatus for measuring the surface tension of a liquid by registering the force necessary to detach a metal ring from the surface.

TENSION TEST. Next to hardness tests, tension tests are the most frequently used to determine the mechanical properties of metals. Tension test specimens necessarily vary in form with the product to be tested. A machined cylindrical specimen with threaded or shouldered ends for gripping is used when the material is sufficiently thick. Standard flat specimens are used for flatrolled products. While both types of specimens have a reduced central section to ensure breaking within a measured gage length, wires and certain special shapes such as steel reinforcing bars for concrete are tested in full section without preparation. Special cast test specimens are often attached to castings, or cast separately, and these are generally tested without machining.

The significant loads determined in the test are reported as unit stresses based on the area of the original section (Stress equals load divided by area). The elongation is expressed as percent increase in length of the gage-marked section. The initial gage length is generally 2 inches (5 centimeters), although an 8-inch (20.3-centimeter) gage length is used for certain flat specimens and other gage lengths are used for special specimens. The gage length should be specified when elongation is reported since percent elongation values are higher for short than for long gage lengths.

The elongation measured over a fixed gage length, and the reduction of area of the section at the fracture are measures of ductility. In cylindrical specimens, the area is readily determined from the final diameter at the fracture. The percent reduction of area is then determined as: original area minus final area, divided by original area.

Autographic load-deformation curves are often drawn during the test. From such a curve, the modulus of elasticity, proportional limit, and yield strength can be determined.

A typical curve has an essentially linear portion (*OA*) in which the deformation is proportional to the applied load. See Fig. 1. It follows that the unit stress (load divided by original area) is proportional to the unit strain (deformation divided by original gage length) in accordance with Hooke's Law. The numerical value of this ratio (e.g., in psi) is known as Young's Modulus or Modulus of Elasticity.

The maximum stress that is developed without deviation from proportionality of stress to strain is the proportional limit (the stress corresponding to load *A*). The maximum stress that can be applied without causing permanent deformation upon release of the load is the elastic limit. Usually, there is little difference between the proportional limit and the elastic limit. Both are dependent on the sensitivity of the measuring devices used and certain details of testing technique. For this reason, the yield strength is generally used as a practical measure of the elastic properties of metals.

The yield strength is the stress at which the stress-strain curve deviates from the initial straight line by a specified increment of strain. The yield strength corresponding to the load at *B* is based on the specified strain deviation or offset *e*. The value of *e* may be as low as 0.0001 inch (0.0025 millimeter) of gage length but the most commonly used value is 0.002 inch (0.05 millimeter), or 0.2% strain.

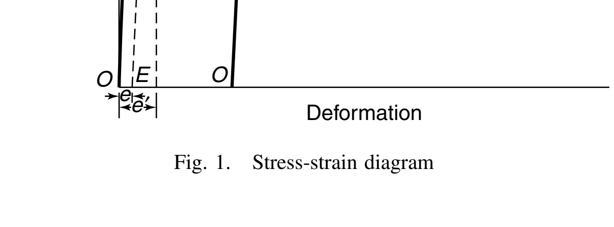

Fig. 1. Stress-strain diagram

If the load should be released after reaching *B*, the load deformation relationship will follow the line *BE*, or a curve line terminating between *O* and *E*. Thus the permanent strain will be *e* or a somewhat smaller value. When the final or permanent strain is specified, the stress is known as the proof stress.

An alternate type of yield strength is based on a specified total extension under load, such as 0.5%. If the specified extension is e' the load B' determines the "extension-underload" yield strength. Load B' may be greater or less than *B*.

The tensile strength, or ultimate tensile strength, is the maximum stress developed in the tension test (load *C* divided by original area).

The breaking stress, corresponding to load *D*, is seldom determined or reported.

In loading tension specimens of many soft irons and steels, a point is reached where stretching continues without increase in load. The unit stress obtained by dividing this load, *F*, by the original area of the section is called the yield point. The elongation of the specimen at the yield point may reach 8% in some instances, after which the load will again increase to a maximum in the normal manner. Upper and lower yield points are indicated at *F*; both are used, but the upper yield point is influenced by variations in testing technique such as alignment of the specimen in the testing machine and speed of test. Yield points occur only rarely in the nonferrous metals.

Conventional stress-strain curves are necessarily similar to the load-deformation curves from which they are derived. True stress-strain curves can also be derived in which the stress is based on the actual or instantaneous area of the cross-section. Such curves do not have a maximum corresponding to *C*, but increase continuously to the breaking load.

TERBIUM. [CAS: 7440-27-9]. Chemical element symbol Tb, at. no. 65, at. wt. 158.92, eighth in the Lanthanide Series in the periodic table, mp 1365°C, bp 3230°C, density 8.230 g/cm^3 (20°C). Elemental terbium has a close-packed hexagonal crystal structure at 25°C. The pure metallic terbium is silver-gray in color, and is stable in ambient air conditions. When pure, the metal is malleable. There is one natural isotope of terbium ^{159}Tb. The isotope is not radioactive and has a low acute-toxicity rating. Seventeen artificial isotopes have been identified. Little is known concerning the characteristics of terbium alloys and intermetallic compounds. Average content of the earth's crust is estimated at 0.9 ppm terbium, making this element the second least abundant of the rare-earth elements. Even at this level, however, terbium is potentially more available than antimony, bismuth, cadmium, or mercury. The element was first identified by C.G. Mosander in 1843. Electronic configuration of the ground state is mixed:

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^8 5s^2 5p^6 5d^1 6s^2.$$

Ionic radius Tb^{3+} 0.93 Å, Tb^{4+} 0.76 Å. Metallic radius 1.783 Å. First ionization potential 5.84 eV; second 11.52 eV. Other physical properties of terbium are given under **Rare-Earth Elements and Metals**. See also **Chemical Elements**.

Terbium occurs in apatite and xenotime and is derived from these minerals as a minor coproduct in the processing of yttrium. Processing involves organic ion-exchange or solvent extraction operations. Elemental terbium is produced by calcium reduction of anhydrous TbF_3 in a reactor under an inert atmosphere. Both the oxides and the metal are available at 99.9% purity.

To date, the uses for terbium have been quite limited. Terbium-activated lanthanum oxysulfide Tb:La_2O_2S is a phosphor finding use as an image intensifier for x-ray screens. Terbium-activated indium borate Tb:$InBO_3$ phosphor emits an intense narrow green light (5,450–5,500 Å) and has found use in information display systems where there are high ambient-light conditions. Future color television tubes may use terbium-activated yttrium silicate Tb:Y_2SiO_5 or yttrium phosphate Tb:YPO_4 green phosphors. They appear to be highly efficient post-deflection focused phosphors for elimination of the need for a shadow mask in a television tube. Although terbium oxide may be used as a stain for ceramics, the compound does not color glass. In soda-lime glass, a small quantity of terbium provides a strong green-blue fluorescence under ultraviolet radiation. Another important use of terbium is in amorphous Tb-Co(fe) alloys for magnetic recording and information storage.

Note: This entry was revised and updated by K. A. Gschneidner, Jr., Director, and B. Evans, Assistant Chemist, Rare-earth Information Center, Institute for Physical Research and Technology, Iowa State University, Ames, IA.

TEREPHTHALIC ACID. [CAS: 100-21-0]. $C_6H_4(COOH)_2$, formula weight 166.13, crystalline solid sublimes upon heating, sp gr 1.510. The compound is almost insoluble in H_2O, only slightly soluble in warm alcohol, and insoluble in ether. Terephthalic acid (TPA) is a high-tonnage chemical, widely used in the production of synthetic materials, notably polyester fibers (poly-(ethylene terephthalate)).

There are several processes for making terephthalic acid on a large scale:

(1) Benzoic acid, phthalic acid and other benzene-carboxylic acids in the form of alkali-metal salts, comprise the chargestock. In a first step, the alkali-metal salts (usually potassium) are converted to terephthalates when heated to a temperature exceeding 350°C. The dried potassium salts (of benzoic acid or *o*- or isophthalic acid) are heated in anhydrous form to approximately 420°C in an inert atmosphere (CO_2) and in the presence of a catalyst (usually cadmium benzoate, phthalate, oxide, or carbonate). The corresponding zinc compounds also have been used as catalysts. In a following step, the reaction products are dissolved in H_2O and the terephthalic acid precipitated out with dilute H_2SO_4. The yield of terephthalic acid ranges from 95 to 98%.

(2) Toluene, formaldehyde, HCl, calcium hydroxide, and HNO_3 comprise the chargestock. In step 1 of this process, the toluene is reacted with concentrated HCl at about 70°C along with paraformaldehyde. This accomplishes chloromethylation of approximately 98% of the toluene. In step 2, saponification of the chloromethyltoluene is effected with lime and H_2O under pressure and at about 125°C. The product is methylbenzyl alcohol. In step 3, the methylbenzyl alcohol is oxidized with HNO_3 (dilute) under a pressure of about 20 atmospheres and at a temperature of about 170°C. The main products are *o*-phthalic acid in HNO_3 solution and insoluble terephthalic acid.

(3) Paraxylene and air comprise the chargestock. These materials, along with a proprietary catalyst and solvent, are fed to a liquid-phase oxidation reactor, operated at moderate pressure and temperature. The reaction is:

$$C_6H_4(CH_3)_2 + 3\ O_2 \longrightarrow C_6H_4(COOH)_2 + 2\ H_2O.$$

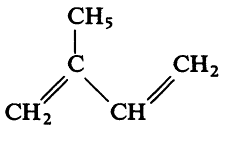
The design details of these processes are proprietary. There are several other processes which essentially are variations of the foregoing descriptions. See also **Intermediate (Chemical)**; **Phthalic Acid**; and **Phthalic Anhydride**.

TERPENE ALCOHOL. A generic name for an alcohol related to or derived from a terpene hydrocarbon, such as terpineol or borneol.

See also **Terpenes and Terpenoids**.

TERPENELESS OIL. An essential oil from which the terpene components have been removed by extraction and fractionation, either alone or in combination. The optical activity of the oil is thus reduced. The terpeneless grades are much more highly concentrated than the original oil (15–30 times). Removal of terpenes is necessary to inhibit spoilage, particularly of oils derived from citrus sources. On atmospheric oxidation the specific terpenes form compounds that impair the value of the oil; for example, *d*-limonene oxidazes to carvone and γ-terpinene to *p*-cymene. Terpeneless grades of citrus oils are commercially available.

TERPENES AND TERPENOIDS. The class of organic compounds known as terpenes is characterized by the presence of the repeating carbon skeleton of isoprene:



These compounds are widely distributed in nature. The name *terpene* used properly refers to the hydrocarbons which are exact multiples of the skeletal isoprene unit. However the name "terpene," sometimes used loosely, includes not only hydrocarbons but also other functional types of naturally occurring organic compounds which contain the reoccurring isoprene skeleton. In the strictest sense, the names *terpenoid* or *isoprenoid* should be used instead of the more loosely applied usage of terpene.

Terpenoids are divided into subclasses as follows:

Subclass name	No. of carbon atoms	No. of isoprene skeletal units
Hemiterpenoids	C_5	1
Monoterpenoids	C_{10}	2
Sesquiterpenoids	C_{15}	3
Diterpenoids	C_{20}	4
Sesterterpenoids	C_{25}	5
Triterpenoids	C_{30}	6
Tetraterpenoids	C_{40}	8
Polyterpenoids	$(C_5)^n$	n

Together they possess a wide variety of functional groups and structures. Nearly every common functional group is represented. Acyclic, monocyclic and polycyclic structures are observed. The greatest structural variation within a single subclass is to be found among sesquiterpenoids.

The combination of skeletal isoprene units in a regular fashion was exemplified early in the study of terpenoids by nearly all of these compounds. On the basis of this regularity the *regular isoprene rule* was formulated and was taken to mean that terpenoids would possess structures built from a regular "head-to-tail" arrangement of isoprene units. However, as structures of more terpenoids were elucidated, departures from the regular rule were observed. In time "irregular" structures were also accommodated through postulated rearrangement of a regular isoprenoid chain to the "irregular" isoprene skeleton. Rearrangements could occur subsequent to or concommitant with natural cyclization. Thus, the adaptation of the *regular isoprene rule* now finds expression in the *biogenetic isoprene rule*, a rule which is supported experimentally. Particularly significant examples of naturally occurring compounds conforming to the biogenetic isoprene rule are lanosterol, a triterpenoid alcohol associated with cholesterol in wool fat, and gibberelic acid, an important plant-growth regulating substance which is the product of a diterpenoid precursor.

The various terpenoid subclasses are not equally distributed in nature. Representatives of the low-molecular weight end of the terpenoid spectrum are seldom encountered as stable isolable natural products. Isoprene itself has not been detected in plants or animals, but the existence of two highly reactive hemiterpenoid substances in living cells is well established. These are the isomeric γ,γ-dimethylallyl pyrophosphate and isopentenyl pyrophosphate, the two being ubiquitous in living organisms and represent the fundamental isoprene building block in terpenoid biogenesis. One source of evidence for the existence of these hemiterpenoids is the presence of the γ,γ-dimethylallyl unit as a substituent of other classes of natural products, often phenols. The origin of these truly vital hemiterpenoids has been found to be mevalonic acid (3,5-dihydroxy-3-methylpentonoic acid), a six-carbon acid produced by the coenzyme A-assisted condensation of three moles of acetic acid. Decarboxylation and dehydration of mevalonic acid pyrophosphate are known to give the five-carbon unit of isopentenyl pyrophosphate. Isopentenyl pyrophosphate and γ,γ-dimethylallyl pyrophosphate are not only the links between the various subclasses of terpenoids but also biogenetically connect seemingly unrelated plant constituents such as steroids and some types of phenolics and alkaloids.

Monoterpenoids and to a lesser extent sesquiterpenoids are the chief components of the volatile oils readily obtained by the distillation of leaves, wood, and blossoms of a broad array of plants. Sesquiterpenoids are among the most universally distributed natural products. Iridolactone, a monoterpenoid, occurs as a defensive secretion of an ant species belonging to the genus *Iridomyrmex*. The iridoids, which is the general name given to the structural type exemplified by iridolactone, make up an important group of monoterpenoids. Another representative of this group is loganin which along with the amino acid tryptophan provides the carbon atoms of a group of indole alkaloids. Medically important quinine and reserpine are members of this group of alkaloids. The "resin acids" are a group of diterpenoid carboxylic acids which form the major nonvolatile part of natural resins often obtained from conifers. Examples are abietic, pimaric and isopimaric acids. Sesterterpenoids, the most recently discovered terpenoid subclass,

are produced by insects and fungi. The tricyclic cereoplasteric acid has been isolated from the waxy coating secreted by the insect *Cereoplastes albolineatus*. The fungus responsible for the leaf spot disease in corn produces the acyclic geranylnerolidol and the tricyclic ophiobola-7, 18-dien-3α-ol. Triterpenoids are found mainly in plants where they occur in resins and plant sap as free triterpenoids, esters or glycosides. A few are observed in animal sources, for example, the acyclic squalene and the tricyclic lanosterol. The connection between squalene and lanosterol is a vitally important one since these two triterpenoids, along with the hemiterpenoid isopentenyl pyrophosphate, are intermediates in the mevalonic acid based biogenesis of steroids. Tetraterpenoids are frequently referred to as *carotenoids*. These constitute a group of natural pigments containing long systems of conjugated carbon-carbon double bonds which are responsible for their color. β-Carotene is the principal pigment of the carrot but this pigment has been isolated from other plant sources also. See also **Carotenoids**. Finally the presence of polyisoprenoids (natural rubber and gutta-percha) in nature shows that the isoprene unit, like the simple sugar and amino acids, has been used to form linear macromolecules.

The use of terpenoids, usually as mixtures prepared from plants, dates from antiquity. The several "essential oils" produced by distillation of plant parts contained the plant "essences." These oils have been employed in the preparation of perfumes, flavorings, and medicinals. Examples are: oils of clove (local anesthetic in toothache), lemon (flavoring), lavender (perfume), and juniper (diuretic). Usually essential oil production depends on a simple technology which often involves steam distillation of plant material. The perfume industry of Southern France uses somewhat more sophisticated procedures in the isolation of natural flower oils since these oils are heat sensitive. The separation of oils from citrus fruit residues in California and Florida is done by machine.

The oleoresinous exudate or "pitch" of many conifers, but mainly pines, is the raw material for the major products of the naval stores industry. The oleoresin is produced in the epithelial cells which surround the resin canals. When the tree is wounded the resin canals are cut. The pressure of the epithelial cells forces the oleoresin to the surface of the wound where it is collected. The oleoresin is separated into two fractions by steam distillation. The volatile fraction is called "gum turpentine" and contains chiefly a mixture of monoterpenes but a smaller amount of sesquiterpenes is present also. The nonvolatile "gum rosin" consists mainly of the diterpenoid resin acids and smaller amounts of esters, alcohols and steroids. "Wood turpentine," "wood rosin" and a fraction of intermediate volatility, "pine oil" are obtained together by gasoline extraction of the chipped wood of old pine stumps. "Pine oil" is largely a mixture of the monoterpenoids terpineol, borneol and fenchyl alcohol. "Sulfate turpentine" and its nonvolatile counterpart, "tall oil," are isolated as by-products of the kraft pulping process. "Tall oil" consists of nearly equal amounts of saponified fatty acid esters and resin acids.

Turpentine is used in syntheses by the chemical and pharmaceutical industries. It also is used as a paint thinner and as a component of polishes and cleaning compounds. Pine oil finds application as a penetrant, wetting agent and preservative, especially by the textile and paper industries, and as an inexpensive deodorant and disinfectant in specialty products. The resin acids are used in the production of ester gum, "Glyptal" resins and are indispensable in paper sizing.

A few individual terpenoids, as well as less expensive mixtures of these compounds, find practical applications. Some examples are: the diterpenoid Vitamin A, the sesquiterpenoid santonin (as an anthelmintic), and the pyrethrins, pyretholone esters of the monoterpenoid chrysanthemic acid (used as an insecticide). A number of sesquiterpenoid lactones of the germacranolide, guaianolide and elemanolide types have shown promise as tumor inhibitors.

The different terpenoid content of plants has served as a finger printing method helpful in botanical identification, especially in cases where differentiation by morphological characteristics has failed. The striking difference in the chemotaxonomy of Jeffery and ponderosa pines serves as an example. The turpentine from the former species consists almost entirely of the paraffinic hydrocarbon n-heptane. Turpentine from ponderosa pine consists largely of the monoterpenes β-pinene and Δ^3-carene.

Besides being of considerable biochemical and botanical interest and of importance in the industrial arts, the food, perfumary, and pharmaceutical trades, the terpenoids have been also a continuing challenge to the organic chemist. The earliest work on the volatile oils was very difficult since the oils were usually complex mixtures and as a consequence individual compounds were isolated as liquids of uncertain purity. Physical constants such as molecular refraction and melting points of solid derivatives, especially those from which the compound could be regenerated were of importance in structural investigations. Organic chemistry relied heavily on oxidative degradation techniques. Dehydrogenation of cyclic terpenoids to aromatic systems and the synthesis of these aromatics played an important role in structure determination. In recent times much of the previous difficulty of obtaining pure samples of terpenoids has been overcome through the use of various chromatographic techniques. Gas-liquid phase chromatography has been used to good advantage in separating both microgram quantities and much larger amounts of the more volatile monoterpenoids and sesquiterpenoids. Much of the type of information formerly obtained only be degradative procedures and dehydrogenations can now be obtained through mass spectrometry. Through nuclear magnetic resonance, infrared and ultraviolet spectrometry, structural information can be obtained in a small fraction of the time that was formerly needed to gain the same amount of information.

Acid-promoted cyclization of acylic terpenoids is common. Geraniol, or more readily its trans isomer nerol, can be cyclized with acids to p-menthane derivatives. More importantly, citral, 2,6-dimethyl-2-octen-8-al, when condensed with acetone gives pseudoionone. The latter when cyclized with acid gives a mixture of α- and β-isomers which in turn are used in the preparation of perfumes, as an intermediate in a number of industrial syntheses of Vitamin A, and also in a commercial synthesis of the plant hormone abscisic acid. Polyclic terpenoids are prone to rearrangement of the carbon skeleton. The acid catalyzed rearrangement of the monoterpene camphene to derivatives of isobornyl alcohol are well known and have been the subject of extensive theoretical studies. Diterpenoids and triterpenoids undergo "backbone" rearrangement through the migration of hydride and methyl groups. Frequently these migrations are stereospecific and are acid promoted.

Studies of terpenoid chemistry have also involved syntheses. Several of the complex sesquiterpenoid structures have been confirmed or, in some cases, correctly established through synthesis. Many elegant new general synthetic methods have been developed as a result of attempts to synthesize terpenoids. The chemistry of terpenoids present a continually growing area of chemical research, perhaps the equal of any in complexity, subtlety, and variety.

TESTING (Chemical). Identification of a substance by means of reagents, chromatography, spectroscopy, melting and boiling point determination, etc.

See also **Analysis (Chemical)**.

TESTING (Physical). Application of any procedure whose object is to determine the physical properties of a material. There are four major categories of tests: (1) Those that are direct measurements of a property, e.g., tensile strength. (2) Those that subject the material to actual service conditions; these often require a long period of time, e.g., shelf life of foods and corrosion of metals. (3) Accelerated tests, which require specially designed equipment that simulates service conditions on an exaggerated scale; in these, only a few hours are necessary to duplicate years of service life, e.g., oxygen bomb aging of elastomers. (4) Nondestructive testing by N-ray of radiography. Elaborate standard testing procedures are established by the American Society for Testing and Materials: http://www.astm.org.

The more common types of tests are as follows:

- Abrasion (elastomers, textiles).
- Adhesion (glues, resins).
- Aging (elastomers, plastics, leather, food products).

- Color stability (pigments, organic dyes) (exposure).
- Corrosion (metals, alloys) (exposure).
- Dielectric (electrical tapes, plastics, glass).
- FLammability (textiles, fibers, paper, plastics).
- Flash point of combustible liquids (Tag closed cup TCC, Cleveland open cup COC, open cup OC.
- Hardness (metals, elastomers, plastics) (Brinell, Rockwell, Shore penetration).
- High temperature (elastomers, adhesives).
- Impact strength (composites, glass cement).
- Sun-cracking (paints, varnishes, elastomers) (exposure).
- Tear (paper, rubber, textiles).
- Tensile strength (fibers, elastomers, paper, textiles, metals).
- Viscosity (lubricants) (Saybolt, Engler).

See also **Nondestructive Testing (NDT)**.

TESTING (Physiological). Determination of the toxicity of a substance or product by administering it to laboratory animals in controlled dosages, by mouth, skin application, or injection. Materials commonly subjected to such evaluation are pharmaceuticals, pesticides, and foods. Extensive testing programs are required before such products are approved for human use.

TESTOSTERONE. See **Hormones**; **Steroids**.

TETRADYMITE. A mineral, bismuth tellurium sulfide, corresponding to the formula Bi_2Te_2S. It is rhombohedral. Tetradymite occurs usually in gold quartz veins. It is found in Norway, Sweden, England, Bolivia, British Columbia; and in the United States, in Virginia, North Carolina, Georgia, Montana, Colorado, and elsewhere. It derives its name from the Greek word meaning fourfold, in reference to the double twin crystals occasionally developed.

TETRAHEDRITE. A mineral of the composition, $(Cu, Fe)_{12}As_4S_{13}$, isomorphous with tennantite. The color ranges from steel-gray to iron-black. The mineral frequently contains cobalt, lead, mercury, nickel, silver, or zinc in replacement of the copper. Tetrahedrite usually occurs in tetrahedral crystals associated with copper ores. The mineral is considered an important copper ore and sometimes is a valuable ore for silver. The mineral sometimes is referred to as *fahlore, gray copper ore*, and *stylotypite*.

THALLIUM. [CAS: 7440-28-0]. Chemical element symbol Tl, at. no. 81, at. wt. 204.38, periodic table group 3, mp 303.5°C, bp 1447–1467°C, density 11.85 g/cm^3 (20°C). Elemental thallium has a hexagonal close-packed crystal structure normally, but also exhibits a face-centered cubic crystal structure.

Thallium metal is bluish-gray upon fresh exposure, changing to dark gray on standing, this oxidation increased with temperature above 25°C; soft, and may be easily cut with a knife. It is malleable but of low tenacity, so that it must be extruded to form wire; HNO_3 is the best solvent; forms alloys with many metals, e.g., mercury, cadmium, zinc, silver, copper, magnesium.

The element was first identified by Sir William Crookes spectrographically in 1861. While seeking tellurium, Crookes observed the characteristic bright green lines in the emission spectrum of thallium. At just about the same time, A. Lamy identified the element. Thallium occurs naturally as ^{203}Tl and ^{205}Tl. Eleven radioactive isotopes have been identified ^{198}Tl through ^{202}Tl, ^{204}Tl, and ^{206}Tl through ^{210}Tl. With exception of ^{204}Tl which has a half-life of 4.07 years, the other isotopes have relatively short half-lives expressed in minutes, hours, and days. See also **Radioactivity**. Thallium is not considered an abundant element, estimates of occurrence in the earth's crust ranging from 0.3 to 3.0 ppm. In a list of 65 chemicals found in seawater, thallium does not appear. First ionization potential 6.106 eV; second, 20.32 eV; third, 29.7 eV. Oxidation potentials $Tl \longrightarrow Tl^+ + e^-$, 0.336 V; $Tl^+ \longrightarrow Tl^{3+} + 2e^-$, −1.25 V; $Tl + OH^- \longrightarrow TlOH + e^-$, 0.3445 V; $TlOH + 2OH^- \longrightarrow Tl(OH)_3 + 2e^-$, 0.05 V. Electron configuration $1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}4f^{14}5d^25p^65d^{10}6s^26p^1$. Other important physical properties of thallium are given under **Chemical Elements**.

Thallium occurs in small amounts in pyrite, zinc blende, and hematite of certain localities, and in a few rare minerals in Sweden and Macedonia. For the recovery of thallium from the flue dust of pyrite burners, the dust is boiled with H_2O, allowed to stand some time, filtered, and HCl added to the filtrate, whereupon crude thallous chloride is precipitated. This is purified by further treatment, and thallium metal obtained (1) by electrolysis of the sulfate solution or (2) by fusion of the chloride with sodium cyanide and carbonate.

Uses

Because thallium is recovered from smelting lead and zinc concentrates, it is available to fulfill any new uses up to several thousand pounds per year. To date, practical applications have been relatively limited. Thallium-activated sodium iodide crystals find use in photomultiplier tubes. It has been learned that thallium bromoiodide crystals transmit infrared radiation and that crystals of thallium oxysulfide detect infrared radiation. A combination of these crystals has been used in military communication systems. Because of their density, both thallous formate and thallous malonate have been used in the preparation of heavy-liquid sink-float solutions used in the gravity separation of minerals. Mixtures of thallium, arsenic, sulfur, and selenium form low-melting-point glasses for encapsulation of semiconductors has been under investigation. It has been found that the addition of small amounts of thallium to the counterelectrode alloy used in selenium rectifiers will improve the performance of the rectifiers. Claims have been made that the addition of a thallium salt to absorb traces of oxygen in tungsten-filament incandescent lamps will increase lamp life. Also, it has been shown that the addition of thallium to various glass formulations will improve optical properties and increase the refractive index.

For a number of years, thallium sulfate had been used in rodenticides. Some use of thallium has been made in connection with alloys for low-temperature applications, particularly for switches, seals, and thermometers. The ternary eutectic mercury-thallium-indium alloy has a freezing point of −63.3°C, while the binary eutectic mercury-thallium alloy has a freezing point of −60°C. These freezing points are considerably lower than that of mercury usually used for similar applications at higher temperatures. Mercury freezes at −38.87°C.

Toxicity

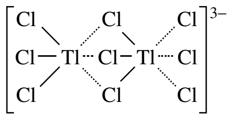
Thallium and thallium compounds are toxic and skin contact must be avoided. Impervious gloves and aprons should be worn and excellent ventilation and masks should be provided where dusts and fumes may be present.

Chemistry and Compounds

Oxidation states: thallous, Tl^+; thallic, Tl^{3+}.

Because of low oxidation potential of thallium to form Tl^+, thallium is quite reactive, dissolving slowly in most dilute mineral acids to form thallium(I) solutions. The thallium(I) halides are insoluble in water, but thallium trihalides are soluble; the latter are formed by treatment of the thallium(I) halide in solution with the corresponding halogen. Thallium(III) iodide, however, does not exist, TlI_3 being $[Tl^+][I_3^-]$.

Thallium(III) compounds are readily reduced to the thallium(I) state (see difference in oxidation potentials above) and are thus fairly strong oxidizing agents. Thallium(I) compounds resemble those of the alkali metals in many respects, including a soluble, strong basic hydroxide (TlOH) ($K_B = 0.14$), a soluble carbonate (Tl_2CO_3), the formation of well crystallized salts, including those with complex anions, the formation of polysulfides (Tl_2S_5), and polyiodides (thus TlI_3 contains the monovalent metal ion, like rubidium iodide, RbI_3 and cesium iodide, CsI_3). Thallium(I) ion resembles silver in forming insoluble halides, sulfide and chromate. The thallium(I) ion forms only weak complexes (probably because of its larger size and low charge) but the thallium(III) ion forms strong ones. There are four complex chloro ions $[TlCl_4]^-$, $[TlCl_5]^{2-}$, $[TlCl_6]^{3-}$, and $[Tl_2Cl_9]^{3-}$, the last having the six-coordinated structure



The complex compounds include the chelates, such as the oxine chelate, and also such compounds as $Tl(TlCl_4)$, $Tl_3(TlBr_6)$, $TlCl_3 \cdot 3NH_3$, $14Rb_3TlBr_6 \cdot 16H_2O$ (here the presence of the ion $[Tl(H_2O)_8]^+$ has been shown), oxalates, such as $H[Tl(C_2O_4)_2]$ (dioxalatothallic acid),

K2[Tl(C_2O_4)$_2$(NO_2)$_2$] $\cdot H_2O$ and a number of complex hydrides, as well as the unstable binary hydride TlH_3.

The most readily prepared organometallic compounds are the dialkyl ones of the type R_2TlX, where X is an acid radical accompanying the ion $[R_2Tl]^+$. The trialkyl compounds of the type TlR_3 are immediately decomposed by H_2O, giving RH and R_2TlOH, in which the thallium atom is isoelectronic with the mercury atom in R_2Hg, and which is a strong base: $(C_2H_5)_2TlOH$, $K_B = 0.90$.

THEORETICAL PLATE. Any contacting device in a fractionating column, such as packing, grids, or screens, that effects the same degree of separation of vapor from liquid as one simple distillation. A column that gives the same separation as 10 successive simple distillations is considered to have 10 theoretical plates. The effectiveness of a fractionating column is measured in terms of theoretical plates. As many as 100 theoretical plates are used in laboratory and industrial operation. The total column height divided by the number of theoretical plates is known as HETP (height equivalent to a theoretical plate). This concept is also used in chromatographic techniques.

THERMAL CRACKING. See **Cracking Process**.

THERMAL EXPANSION COEFFICIENT. The change in volume per unit volume per degree change in temperature (cubical coefficient). For isotropic solids the expansion is equal in all directions, and the cubical coefficient is about three times the linear coefficient of expansion. These coefficients vary with temperature, but for gases at constant pressure the coefficient of volume expansion is nearly constant and equals 0.00367 for each degree Celsius at any temperature.

THERMAL INSULATION. See **Insulation (Thermal)**.

THERMAL RADIATION. All bodies that are not at absolute zero emit radiation excited by the thermal agitation of their molecules or atoms, whether there are other causes of excitation or not. This thermal radiation ranges in wavelength from the longest infrared to the shortest ultraviolet rays, its spectral energy distribution, however, depending upon the nature of the body and upon its temperature. The total emissive power of a surface at any temperature is the rate at which it emits energy of all wavelengths and in all directions, per unit area of radiating surface. The flux density (per unit solid angle) in various directions obeys the cosine emission law approximately; but strictly only in the case of a black body.

THERMIONIC CONVERSION. The process whereby electrons released by thermionic emission are collected and utilized as electric current. The simplest example of this is provided by a vacuum tube, in which the electrons released from a heated anode are collected at the cathode or plate. Used as a method of producing electrical power for spacecraft.

THERMIONIC EMISSION. Direct ejection of electrons as the result of heating and material, which raises electron energy beyond the binding energy that holds the electron in the material.

THERMITE. A mixture of ferric oxide and powdered aluminum, usually enclosed in a metal cylinder and used as an incendiary bomb, invented by the German chemist Hans Goldschmidt around 1900. On ignition by a ribbon of magnesium, the reaction produces a temperature of 2200°C, which is sufficient to soften steel. This is typical of some oxide/metal reactions that provide their own oxygen supply and thus are very difficult to stop.

THERMOCHEMISTRY. That aspect of chemistry which deals with the heat changes which accompany chemical reactions and processes, the heat produced by them, and the influence of temperature and other thermal quantities upon them. It is closely related to chemical thermodynamics. The heat of formation of a compound is the heat absorbed when it is formed from its elements in their standard states. An exothermic reaction evolves heat; and endothermic reaction requires heat for initiation.

THERMOCOUPLE. In 1821, Seebeck discovered that an electric current flows in a continuous circuit of two metals if the two junctions are at different temperatures, as shown in Fig. 1. A and B are two metals, T_1 and T_2 are the temperatures of the junctions. I is the thermoelectric current. A is thermoelectrically positive to B if T_1 is the colder junction. In 1834, Peltier found that current flowing across a junction of dissimilar metals causes heat to be absorbed or liberated. The direction of heat flow reverses if current flow is reversed. Rate of heat flow is proportional to current but depends upon both temperature and the materials at the junction. Heat transfer rate is given by PI, where P is the Peltier coefficient in watts per ampere, or the Peltier emf in volts. Many studies of the characteristics of thermocouples have led to the formulation of three fundamental laws:

1. *Law of the Homogeneous Circuit.* An electric current cannot be sustained in a circuit of a single homogeneous metal; however it may vary in section, by the application of heat alone.
2. *Law of Intermediate Metals.* If in any circuit of solid conductors the temperature is uniform from any point P through all the conducting matter to a point Q, the algebraic sum of the thermoelectromotive forces in the entire circuit is totally independent of this intermediate matter and is the same as if P and Q were put in contact.
3. *Law of Successive or Intermediate Temperatures.* The thermal emf developed by any thermocouple of homogeneous metals with its junctions at any two temperatures T_1 and T_3 is the algebraic sum of the emf of the thermocouple with one junction at T_1 and the other at any other temperature T_2 and the emf of the same thermocouple with its junctions at T_2 and T_3. See Fig. 2.

Common thermocouple wire combinations used in industry are listed in Table 1. A choice of different metals is needed to fulfill a broad range of temperatures as well as for oxidizing or reducing conditions in use. The temperature-thermal emf curves for common types of thermocouples are

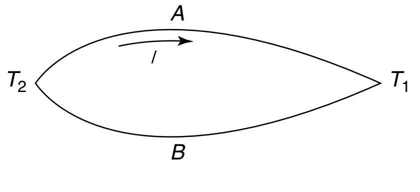

Fig. 1. Simple thermocouple circuit

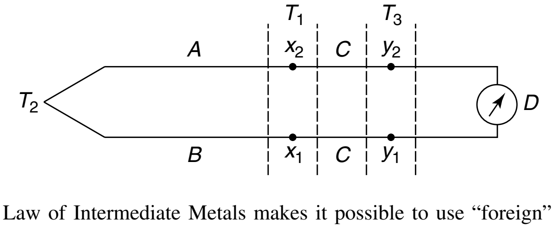

Fig. 2. Law of Intermediate Metals makes it possible to use "foreign" wires to connect thermocouple to measuring instrument. Thermocouple materials A and B can be connected to the instrument by use of connecting materials C and D. If the temperatures at X_1 and X_2 are both at T_1 and if temperatures at Y_1 and Y_2 are both at T_3, the emf of the circuit will be independent of materials C and D

TABLE 1. COMMONLY USED THERMOCOUPLES AND TEMPERATURE RANGES

ANSI type	Positive element	Negative element	Normal temperature range °F	°C
B	Platinum 20% Rhodium	Platinum 6% Rhodium	1,600–3,100	870–1,700
E	Chromel	Constantan	32–1,600	0–870
J	Iron	Constantan	32–1,400	0–760
K	Chromel	Alumel	32–2,300	0–1,260

S	Platinum 10% Rhodium	Platinum	32–2,700	0–1,480
T	Copper	Constantan	−300– +700	−180– +370

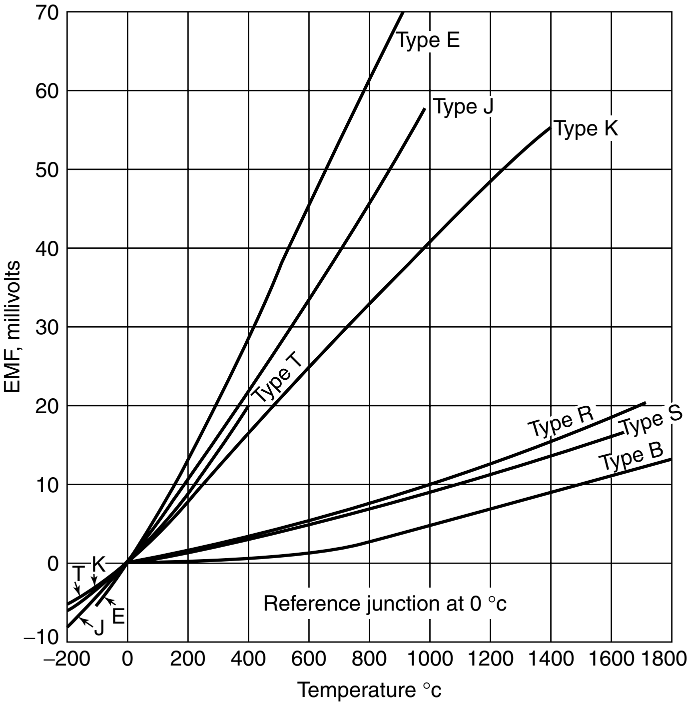

Fig. 3. Temperature-thermal emf curves for common types of thermocouples. (*Honeywell*)

given in Fig. 3. The hot junction of a thermocouple may be joined by any means that will ensure good electrical continuity when in use. Commonly, the two wires are twisted together and either welded or silver-soldered. Simple clamping of wires together provides adequate connection for short-term use in clean atmospheres at lower temperatures. For industrial applications, the thermocouple is usually placed within a protecting tube. A typical assembly is shown in Fig. 4. For lower temperatures, carbon steel may be used. As the temperature goes up, wrought iron, stainless steel, nickel, nickel-chromium-iron, fused silica, silica-alumina, silicon carbide, alumina, and beryllia may be used. Beryllia protecting tubes will withstand operating temperatures of up to 4,000°F (~2,200°C). For some applications, disposable-tip thermocouples have been developed. These are particularly effective for high-temperature molten-metal temperature measurements.

The emf developed by a thermocouple depends upon the temperature of both the measuring and reference junctions. Thus, to determine temperature, the following data must be known: (1) the calibration data for the particular thermocouple; (2) the measured emf; and (3) the temperature of the reference junction. In laboratory cases, the reference junction can be maintained at the freezing temperature of water. However, in most modern instruments, the ambient temperature of the reference junction is sensed, and the correction is incorporated in the measurement circuitry.

Multiple thermocouples may be used in parallel and connected to a single instrument. A typical application is a fire-warning system. Multiple

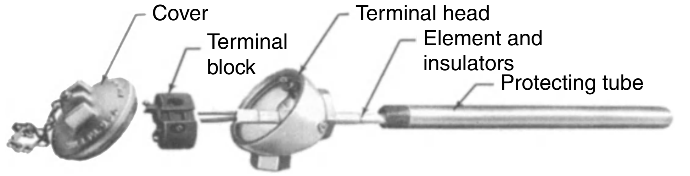

Fig. 4. Assembly of industrial thermocouple, terminal block, and protecting tube. (*Honeywell*)

thermocouples also may be connected in series. This is a means for obtaining the average temperature of an object. Also two or more thermocouples may be connected in series so that the emf outputs of the couples are additive. In application installations, thermopiles sometimes are used to detect the presence or absence of the pilot flame and cause a relay to turn off the main gas supply valve.

THERMODYNAMICS. Classical thermodynamics is a theory which on the basis of four main laws and some ancillary assumptions deals with general limitations exhibited by the behavior of macroscopic systems. Phenomenologically it takes no cognizance of the atomic constitution of matter. All *mechanical* concepts such as kinetic energy or work are presupposed. Thermodynamics is motivated by the existence of dissipative mechanical systems. A *thermodynamic system* K may be thought of as a collection of bodies in bulk; when its condition is found to be unchanging in time (on a reasonable time scale) it is *in equilibrium.* It is then characterized by the values of a finite set of, say, n physical quantities, it being supposed that none of these is redundant. Such a set of quantities constitutes the *coordinates* of K, denoted by $x(= x_1, \dots, x_n)$. Any set of values of these is a *state* $\mathscr{S}$ of K. In virtue of these definitions, K is in a state only when it is in equilibrium. The passage of K from a state $\mathscr{S}$ 1 to a state $\mathscr{S}'$ is a *transition* of K. A transition is *quasi-static* if in its course it goes through a continuous sequence of states, and if the forces that do work on the system are just those which hold it in equilibrium. A transition is *reversible* if there exists a second transition that restores the initial state, the final condition of the surroundings of K being the same as the initial condition. Reversible transitions are assumed to be quasi-static.

An enclosure, such that the equilibrium of a system contained within it can only be disturbed by mechanical means, is *adiabatic*, otherwise it is *diathermic*. For instance, stirring, or the passage of an electric current, constitute "mechanical means." A system K_0 in an adiabatic enclosure is *adiabatically isolated*, but this does not preclude mechanical interactions with the surroundings. Its transitions are then called adiabatic.

For the time being, the masses of all substances present will be supposed fixed, and to achieve simplicity it will be given that (1) there are no substances present whose properties depend on their previous histories, and (2) capillary forces as well as long-range interactions are absent. Further, it will be supposed that of the n coordinates of K, just $n - 1$ have geometrical character (*deformation coordinates*, e.g., volumes of enclosures), so that the work done by K in a quasi-state transition is

$$\int dW = \int \sum_{k=1}^{n-1} P_k(x)dx_k \tag{1}$$

Such a system will be called a *standard system* ($n - 1$ enclosures in diathermic contact, each containing a simple fluid, may serve as example, x_n being any one of the pressures).

The Zeroth Law

Suppose two systems $K_A(x)$ and $K_B(y)$ to be in mutual diathermic contact. Experience shows that the states $\mathscr{S}_A$ and $\mathscr{S}_B$ cannot be assigned arbitrarily,

but that there exists a necessary relation of the form

$$f(x;y) \equiv f(x_1,\ldots,x_n;y_1,\ldots,y_m)=0 \tag{2}$$

between them. If K_C is a third system, its diathermic equilibrium with K_B on the one hand, or with K_A on the other, is governed by conditions

$$g(y;z)=0 \tag{3}$$

and

$$h(z;x)=0 \tag{4}$$

respectively. That these three functions are not independent is expressed by the *Zeroth Law: If each of two systems is in equilibrium with a* third *system then they are in equilibrium with each other*. It follows that any two of Equations (2) through (4) imply the third, i.e., they must be equivalent to equations of the form

$$\xi(x)=\eta(y)=\zeta(z) \tag{5}$$

Thus, with each system there is now associated a function, its *empirical temperature function*, such that two systems can be in equilibrium if and only if their *empirical temperatures* (i.e., the values of their empirical temperature functions) are equal. Write $t=\xi(x)$; so that one has the *equation of state* of K_A. Also, t may be introduced in place of any one of the x_k. Note that the empirical temperature is not uniquely determined since $t_A=t_B$ may be replaced by $\phi(t_A)=\phi\,(t_B)$ where the function ϕ is monotonic but otherwise arbitrary: one has a choice of *temperature scales*. For a system not in equilibrium, temperature is not defined.

The First Law

It is obvious that one can do mechanical work upon a system (say by stirring) while its initial and final states are the same. (Nothing is being said about the surroundings!) In this sense mechanical energy is not conserved. One might, however, hope that it is conserved at least in a restricted class of transitions. That this is so is asserted by the *First Law: The work W_0 done by a system K_0 in an adiabatic transition depends on the terminal states alone*. Thus, if $\mathscr{S}'(x')$, $\mathscr{S}''(x'')$ are the terminal states

$$W_0=F(x';x'')$$

If $\mathscr{S}'''(x''')$ is a third state, and the previous transition proceeds via $\mathscr{S}'''$, W_0 must not depend on x''', i.e.,

$$F(x';x''')+F(x''';x'')\equiv F(x';x'')$$

It follows that there must exist a function $U(x)$, defined to within an arbitrary additive constant, such that

$$F(x';x'')=U(x')-U(x'')(=-\Delta U,\text{ say})$$

$U(x)$ is the *internal energy function* of K. (To make sure that U is in fact defined for all states, one assumes that *some* adiabatic transition always exists between any pair of given states.) The energy of a compound standard system is the sum of the energies of its constituent standard systems. Further, U must be a monotonic function of t, and it is convenient to choose the scale of t such that $\partial U/\partial t>0$.

When the transition from $\mathscr{S}'$ to $\mathscr{S}''$ is adiabatic, $W_0+\Delta U$ vanishes by definition of U. If the transition is not adiabatic and W is the work done by K, the quantity

$$\Delta U+W(=Q,\text{ say}) \tag{6}$$

will in general fail to vanish. Q is then called the *heat absorbed* by K. Every element of a quasistatic adiabatic transition is subject to $dQ=0$, i.e., by Equations (1) and (6), to the differential equation

$$\sum_{k=1}^{n-1}\left(P_k(x)+\frac{\partial U(x)}{\partial x_k}\right)dx_k+\frac{\partial U}{\partial t}dt=0 \tag{7}$$

The Second Law

Experiment shows that if $\mathscr{S}'$ and $\mathscr{S}''$ are arbitrarily prescribed states, then it may be that no adiabatic transition from $\mathscr{S}'$ to $\mathscr{S}''$ exists. When this is the case one says that $\mathscr{S}''$ is *inaccessible* from $\mathscr{S}'$, but $\mathscr{S}'$ is then accessible from $\mathscr{S}''$, as has been already assumed. The states may of course happen to be mutually accessible. The existence of states adiabatically inaccessible from a given state is asserted precisely by the *Second Law: In every neighborhood of any state $\mathscr{S}$ of an adiabatically isolated system there are states inaccessible from $\mathscr{S}$*. (This formulation of the Second Law is known as the *Principle of Carathéodory*.) *A fortiori* this law applies to quasistatic transitions, i.e., those which satisfy Equation (7). It asserts there are states $\mathscr{S}''$ near $\mathscr{S}'$ such that no functions $x_k(t)$ exist which satisfy Equation (7) and whose values when $t=t''$ are just x_k'', $(k=1,\ldots,n-1)$. It is merely a mathematical problem (the Theorem of Carathéodory) to prove that this is the case if and only if there exist functions $\lambda\ (x)$ and $s(x)$, $(x_n\equiv t)$ such that the left-hand member is identically equal to λds, where ds is the total differential of s. Thus, the Second Law entails that

$$dQ=dU+dW=\lambda ds \tag{8}$$

(dQ is of course not a total differential), s is called the *empirical entropy function of* K. It is not uniquely determined, since it may be replaced by any monotonic function of s. If two standard systems K_A and K_B in diathermic contact make up a compound system K_C; $dQ_C=dQ_A+dQ_B$, i.e., because of Equation (8),

$$\lambda_A ds_A+\lambda_B ds_B=\lambda_C ds_C$$

By including s_A, s_B and the common empirical temperature t among the coordinates of K_C, one infers that

$$\lambda_A=T(t)\theta_A(s_A),\quad \lambda_B=T(t)\theta_B(s_B),$$
$$\lambda_C=T(t)\theta(s_A,s_B)$$

The common function $T(t)$ is called the *absolute temperature function*, while

$$S_A(s_A)=\int\theta_A(s_A)ds_A$$

is the *metrical entropy* of K_A The "element of heat" dQ of any standard system thus splits up into the product of a universal function of the empirical entropy and the total differential $dS(x)$ of the metrical entropy function:

$$TdS=dU+dW \tag{9}$$

By multiplying T by a constant and dividing S by the same constant, T can be arranged to be positive.

If one now chooses $x_n=S$ and recalls that the $x_k(k<n)$ are freely adjustable, the Second Law would be violated if S were also adjustable at will (by means of non-static adiabatic transitions). Taking continuity requirements into account, it follows that S can either never decrease or never increase. The single example of the sudden expansion of a real gas shows that it can never decrease. One has the *Principle of Increase of Entropy: The entropy of an adiabatically isolated system can never decrease*.

The Third Law

It is known from experiment that for given values of the deformation coordinates, the energy function has a lower bound U_0. The question rises whether the entropy S has an analogous property. It is found in practice that the specific heats $\partial U/\partial T$ of all substances appear to go to zero at least linearly with T as $T\to 0$. This ensures that the function S goes to a finite limit S_0 as $T\to 0$. Experiment shows, however, further that as $T\to 0$, the derivatives of S with respect to the deformation coordinates also go to zero. In contrast with U_0, S_0 has therefore the remarkable property that it is independent of the deformation coordinates. One thus arrives at the *Third Law: The entropy of any given system attains the same finite least value for every state of least energy*. One immediate consequence of this is that the so-called *classical ideal gas* (the product of whose volume V and pressure P is proportional to T, and whose energy is a function of T only) cannot exist in nature. Further, no system can have its absolute temperature reduced to zero. The Third Law is therefore a statement about the properties of functions, not of systems, at $T=0$.

The practical applications of the theory just outlined divide themselves into two broad classes: (1) Those which are based on the existence and properties of the functions U and S and some others related to them—all "thermodynamic identities" being merely the integrability condition for the total differentials of these functions; and (2) those which are based on the Principle of Increase of Entropy: the entropy of the actual state of an adiabatically enclosed system being greater than that of any neighboring "virtual" state.

The most important of the auxiliary functions just mentioned are the *Helmholtz Function*:

$$F=U-TS \tag{10}$$

the *Gibbs Functions*:

$$G = U - TS + \sum_{k=1}^{n-1} P_k x_k \tag{11}$$

the *Enthalpy*:

$$H = U + \sum_{k=1}^{n-1} P_k x_k \tag{12}$$

sometimes called *thermodynamic potentials*. Then, e.g.,

$$dF = -SdT - dW$$

F therefore contains all available quantitative information about K, since

$$S = -\frac{\partial F}{\partial G}, \text{ and } P_k = -\frac{\partial F}{\partial x_k} \tag{13}$$

The same is true of G for instance, since

$$S = -\frac{\partial G}{\partial T}, \text{ and } x_k = -\frac{\partial G}{\partial P_k}$$

F and G are naturally taken as functions of $x_1, \ldots, x_{n-1}, T$ and of $P_1, \ldots, P_{n-1}, T$, respectively. At times one speaks of F as the "Helmholtz free energy" and of G as the "Gibbs free energy." In an *isothermal* reversible transition, the amount W of work done by a system is equal not to the decrease of its energy U but to the decrease $-\Delta F$ of its (Helmholtz) free energy. In the presence of internal sources of irreversibility

$$W < -\Delta F$$

In considering physicochemical equilibria, that is to say, if one is interested in the internal constitution of a system in equilibrium when changes of phase and chemical reactions are admitted, one introduces the *constitutive coordinates* n_i^α; this being the number of moles of the ith constituent C_i in the α th phase. The definitions of Equations (10) through (12) remain unaltered, for the n_i^α do not enter into the description of the interaction of the system with its surroundings. Let an amount dn_i^α of C_i be introduced quasistatically into the α th phase of the system. The work done on K shall be $\mu_i^\alpha dn_i$. The quantity μ_i^α so defined is the *chemical potential* of C_i in the α th phase. It is in general a function of all the coordinates of K. Then, identically.

$$dG = \sum_{k=1}^{n-1} x_k dP_k - SdT + \sum_i \sum_a \mu_i^\alpha dn_i^\alpha$$

Integrability conditions such as

$$\partial \mu_i^\alpha / \partial T = -\partial S / \partial n_i^\alpha$$

are applications of the first kind. On the other hand, the minimal property of G, derived from the maximal property of S, requires that

$$\sum_i \sum_a \mu_i^\alpha dn_i^\alpha = 0$$

when all virtual states differ only in the values of the constitutive coordinates. If the system is chemically inert, the dn_i^α are subject only to the requirements of the conservation of matter. One then concludes that if there are c constituents and p phases, i.e., $n + pc$ coordinates in all, then the number f of these to which arbitrary values may be assigned is

$$f = c - p + n$$

This typical application of the second kind is the Gibbs Phase Rule (for inert systems). This rule is often stated merely for systems with only two external coordinates ($n = 2$, e.g., $x_i = P, x_2 = T$). There must then be no internal partitions within the system, nor may it, for instance, contain magnetic substances in the presence of external magnetic fields.

The beauty and power of phenomenological thermodynamics lies just in the generality and paucity of its basic laws which hold independently of any assumptions concerning the microscopic structure of the systems which they govern. Its quantitative content is limited to conditions of equilibrium. Its conceptual framework is too narrow to permit the description of the temporal behavior of systems, except to the extent that it makes it possible to decide which, of any pair of states of an adiabatically enclosed system, must have been the earlier state.

Statistical thermodynamics seeks to remedy these deficiencies by making specific assumptions about the microscopic structure of the system K, and relating its macroscopic behavior to that of its atomic constituents. K is then to be regarded as an *assembly* of a very large number of particles, which, on a non-quantal level, is a mechanical system with, say, N degrees of freedom. A *microstate* of K is a set of values of its N coordinates and its N conjugate momenta. It is out of the question to measure all these at a given time. One therefore constructs a *representative ensemble* ε_K of K, which is an abstract collection of a very large number of identical copies of K. At any time t, the members of ε_K will be in different microstates. Let the fractional number of members of the ensemble whose microstates lie in the range dp, dq about p, be $\phi dpdq$. Then ϕ is the *probability-in-phase*, and with $d\Gamma = dpdq$

$$\int \phi d\Gamma = 1 \tag{14}$$

The reason for this terminology is implicit in the *Postulate: The probability that a given assembly K will, at time t, be in a microstate lying in the range* $d\Gamma$ *about p, q, is equal to the probability* $\phi d\Gamma$ *that the microstate of a member of* ε_K *selected at random at time t, lies in the same range.*

The mean value $\langle f \rangle$ of a dynamical quantity f is defined to be

$$\langle f \rangle = \int f \phi d\Gamma$$

If N is sufficiently large, fluctuations about the mean will usually be negligible.

When K is in equilibrium, ϕ must be constant in time, and this will be the case if it is a function of the (time-independent) Hamiltonian H of K. Ensemble averages are now assumed to coincide with temporal averages. When, in particular, K is in diathermic equilibrium with its surroundings one can show that ϕ must have the form

$$\phi = \exp[(\phi - H)/\phi] \tag{15}$$

where ϕ and θ are independent of p, q. Then

$$\theta \langle \ln \theta \rangle = \phi - \langle H \rangle \tag{16}$$

and, because of Equation (14)

$$d \int \exp[(\phi - H)/\theta] d\Gamma = 0 \langle d[(\phi - H)/\theta]$$

where d refers to a variation of the macroscopic coordinates of K. Using Equation (16) and its variation, the relation

$$-\theta d \langle \ln \phi \rangle = d \langle H \rangle - \langle dH \rangle \tag{17}$$

follows. Now $\langle H \rangle (= \overline{U}$, say) is the total energy of the assembly, while $\langle dH \rangle$ is the average of the change of the potential energy, i.e., the work $-dW$ done by the external forces on K. If one writes

$$\overline{S} = -k \langle \ln \phi \rangle$$

where k is a constant, Equation (17) becomes

$$k^{-1} \theta d\overline{S} = d\overline{U} + dW$$

This is identical with the phenomenological relation of Equation (9) if one formally identifies S with $\overline{S}U$ with $\overline{U}$ and θ with kT. In this way, contact with the phenomenological theory has been established, and the quantities characteristic of the one theory have been *correlated* with that of the other. With this correlation, or interpretation, ϕ becomes F. However, because of Equations (14) and (15)

$$F = -kT \ln \int \exp(-H/kT) d\Gamma$$

so that if only H is known, the integral on the right (the *partition function*), and thus F, can be calculated. The equation of state of a real gas can thus in principle be obtained from a knowledge of the forces operating within the assembly. This illustrates how the additional information put into the theory yields a correspondingly greater output. Phenomenologically, such an equation of state might be written as

$$PV = \sum_{n=1}^{\infty} B_n(T) V^{1-n}$$

but here each of the *virial coefficients* $B_1, B_2, \ldots$ must be measured separately.

THERMOELECTRIC COOLING. Like conventional refrigeration systems, thermoelectric systems obey the same basic laws of thermodynamics. Both in principle and result, thermoelectric cooling has much in common with conventional refrigeration methods. In a conventional refrigeration system, the main working parts are the freezer, condenser, and compressor. The freezer surface is where the liquid refrigerant boils, changes to vapor, and absorbs heat energy. The compressor circulates the refrigerant above ambient level. The condenser helps to discharge the absorbed heat into surrounding ambient. In thermoelectric refrigeration, the refrigerant in both liquid and vapor forms is replaced by two dissimilar conductors. The freezer surface becomes cold through absorption of energy by electrons as they pass from one semiconductor to another, instead of energy absorption by the refrigerant as it changes from liquid to vapor. The compressor is replaced by a direct current power source which pumps the electrons from one semiconductor to another. A heat sink replaces the conventional condenser fins, discharging the accumulated heat energy from the system.

The components of a thermoelectric cooler are indicated by the cross section of a typical unit shown in Fig. 1. Thermoelectric coolers such as this are actually small *heat pumps* that operate on the physical principles well established over a century ago. Semiconductor materials with dissimilar characteristics are connected electrically in series and thermally in parallel, so that two junctions are created. The semiconductor materials are *n*- and *p*-type and are so named because either they have more electrons than necessary to complete a perfect molecular lattice structure (*n*-type), or not enough electrons to complete a lattice structure (*p*-type). The extra electrons in the *n*-type material and the holes left in the *p*-type material are called *carriers* and they are the agents that move the heat energy from the cold to the hot junction.

Heat absorbed at the cold junction is pumped to the hot junction at a rate proportional to carrier current passing through the circuit and the number of couples. Good thermoelectric semiconductor materials, such as bismuth telluride, greatly impede conventional heat conduction from hot to cold areas, yet provide an easy flow for the carriers. In addition, these materials have carriers with a capacity for carrying more heat. Only since the refinement of semiconductor materials in the early 1950s has thermoelectric refrigeration been considered practical for many applications.

In practical use, couples are combined in a module where they are connected in series electrically and in parallel thermally. See Fig. 2. Normally, a module is the smallest component available. The user can tailor quantity, size, or capacity of the module to fit exact requirements without procuring more total capacity than is actually required. Modules are available in a variety of sizes, shapes, operating currents, operating voltages, number of couples, and ranges of heat-pumping levels. The present trend is toward a larger number of couples operating at a low current.

Thermoelectric coolers find three basic categories of applications. (1) Use in electronic components; (2) in temperature control units; and (3) in medical and laboratory instruments.

Modules normally contain from 2 to 71 couples with ceramic-metal laminate plates. If modules are to be used in cooling chambers of large components, a total surface area of virtually any size can be made by placing the appropriate number of modules side by side.

The interfaces at the cold junction and the hot junction must be constructed to transfer heat in and out of the module with little difference in temperature. This is accomplished with metal-ceramic laminate plates that give strength and permit good thermal bonding between the two interfaces. The outer plate surface is usually tinned to facilitate soldering to heat sinks. Where soldering is not practical, as in the case of thermal expansion differences, heat transfer grease is recommended. Epoxy bonding agents are available where a more permanent solderless bond is required.

The single-stage module is capable of pumping heat where the difference in temperature of the cold junction and hot junction is 70°C or less; however, in those applications requiring higher delta T_s, the modules can be cascaded. Cascading is a mechanical stacking of the modules so that the cold junction of one module becomes the heat sink for a smaller module placed on top. In addition to the heat pumped by any given stage, the next lower stage must also pump the heat resulting from the input power to that upper stage. Consequently, each succeeding stage must be larger and larger from the top of the cascade downward.

With any given set of heat sink and cold spot temperatures, there exists an optimum heat-pumping capacity or "size" ratio between each adjacent pair of stages. The optimum size ratio increases as the overall delta T increases, but decreases as the number of stages increases. It is not necessarily a constant from stage to stage, even with delta T and number of stages fixed. True optimization of a cascade design requires accurate temperature-dependent data on the thermoelectric materials in combination with a computerized numerical design theory.

Applications requiring low-temperature thermoelectric coolers usually have strict limitations on available power. Therefore, it is not practical to fabricate and stock numerous different cascades that can be optimized for only one set of conditions. On the other hand, fully optimized prototypes involve engineering and manufacturing costs that may prove uneconomical for some applications. Therefore, a low-cost alternative approach has been developed for responding to such requirements. Standard cascades are fabricated by assembling *partials* of standard modules. The number of

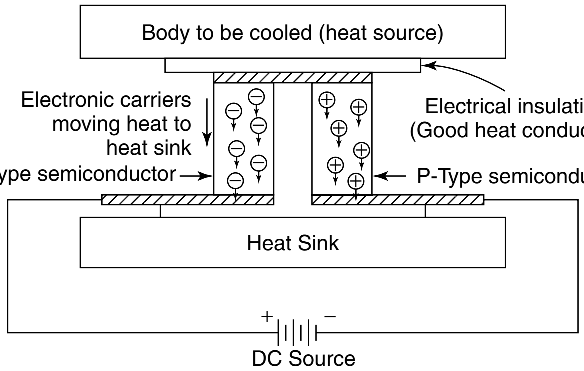

Fig. 1. Cross section of thermoelectric cooler

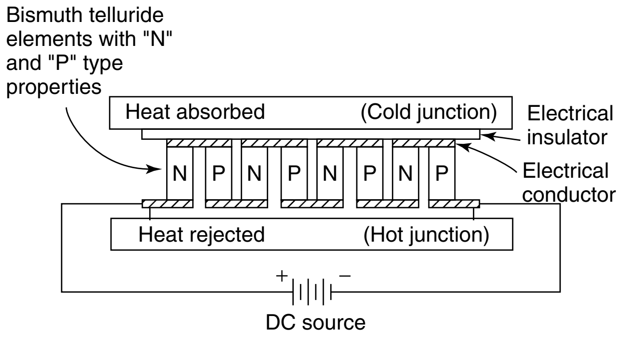

Fig. 2. Thermoelectric module assembly. Elements are electrically in series, thermally in parallel

different standard cascades is virtually unlimited due to "free" variables, such as number of stages, couple distribution, and the basic building block module. In order to determine the best standard cascade for a given application, the desired hot-side temperature, cold-side temperature, and thermal load are entered into a computer system. The result is a list of numerous standard coolers, which meet these specifications with various combinations of input power and cost. Generally, the lowest input power devices are of higher cost and vice versa.

The heat sink design is very important. The heat sink must carry heat away with minimum rise of temperature. It should be stressed that all the thermoelectric cooler does is to move energy from the load to the heat sink where it must be dissipated to another medium, the latter required to be cooler than the hot junction.

Power supply capabilities for thermoelectric coolers range from the simple open-loop direct current supply with a switch to sophisticated feedback systems with close temperature regulation and fast response. The only limitation on the supply is that ripple be maintained at a point lower than 10 to 15%. Open-loop systems will generally contain a transformer, rectifiers, choke, and chassis with heat sink for the rectifiers. In feedback systems, a thermistor is used to sense temperature at the cold junction. This signal is compared with the desired temperature setting to obtain an error signal.

THERMOELECTRICITY. Electricity produced directly by applying a temperature difference to various parts of electrically conducting or semiconducting materials. Usually two dissimilar materials are used, and the points of contact are kept at different temperatures (Peltier effect). Many temperature-measuring devices (thermocouples, thermopiles) work on this principle, since the voltage is proportional to the temperature difference. Metallic conductors are usually used for these "thermometers," which produce a rather small current. A newer use for the effect is as a source of electrical energy, i.e., a means of direct conversion of heat into electricity (or vice versa) without the use of a generator (or motor). The materials used for these thermoelectric couples are semiconductors (e.g., tellurium, zinc antimonide; lead, bismuth, and germanium tellurides; samarium sulfide) or thermoelectric alloys, all of which produce relatively large currents. Several of these "cells" are then hooked in series much like the cells of a battery.

THERMOFOR PROCESS. A moving-bed catalytic cracking process in which petroleum vapor is passed up through a reactor countercurrent to a flow of small beads or catalyst. The deactivated catalyst then passes through a regenerator and is recirculated.

THERMOGRAVIMETRIC ANALYSIS. This analytical technique (TGA), also sometimes referred to as thermogravimetry, is a method whereby the weight and temperature of a sample under test are continuously recorded as the sample is heated at a constant and linear rate. The heating, usually within the range from ambient up to 1,100 or 1,500°C, is achieved by a furnace, which surrounds, but does not touch, the sample. Thus, the sample remains freely suspended from the balancing mechanism, which is actuated as the sample mass alters in response to chemical reactions produced as its temperature is progressively increased. Weight-loss curves are preferably produced by means of an X-Y recorder. Of course, the term *weight-loss* must be used with reservation because in some atmospheres a sample may gain weight. Indirectly, TGA information can be applied to studies of rates of reaction and energies of activation for the reaction, sublimation, or vaporization of chemical compounds and minerals. Weight gains are caused by the adsorption and absorption of gases by solid samples, direct reaction as in oxidation, corrosion, recarbonation, and hydration, or the reaction of gases to produce solids. Conversely, weight losses are produced by the desorption of gases, dehydration, vaporization, sublimation, gaseous desolvation, and gas-liberating reactions of both organic and inorganic substances. Specific fields that have widely used TGA include: studies involving the thermal stability of minerals and mineral mixtures; the pyrolysis of coals, petroleum, and cellulose; the analysis of soils; roasting and calcining; thermochemical reactions of ceramics and cements; dehydration hygroscopicity studies; solid-state reactions; effect of radiation on various materials; corrosion studies; and the detection of short-lived unstable intermediate compounds.

THERMOMETER. An instrument that measures temperature. A thermometer may take advantage of one of several physical properties of materials that change when they are subjected to a change in temperature. Liquids, gases, and solids expand with increasing temperature; decrease in volume with decreasing temperature. Thus, there are liquid-in-glass thermometers, which depend upon the volumetric relation of mercury or other liquids with temperature. The difference in the energy radiating from materials at various temperatures is the basis of optical and radiation pyrometers. Bimetallic thermometers depend upon the differing expansiveness of different metals. Changes in electrical resistance with temperature are utilized in resistance thermometers and thermistors. Thermocouples depend upon the Seebeck, Peltier, and Thomson effects, wherein the emf in an electrical circuit comprising dissimilar metals bears a relationship to the temperature difference between a cold junction and the temperature being measured.

Several kinds of thermometers are described in this volume. See alphabetical index.

THERMOMETER (Filled-System). A representative filled-system thermometer is shown in Fig. 1. The temperature-sensing element (bulb) contains a fluid that changes its volume or pressure with temperature. The pressure-sensitive element (bourdon) responds to these changes by delivering a motion or force to a device that transduces the signal to a usable form. This is commonly a mechanical linkage which drives a pointer or pen, but may be a pneumatic or electric device which transmits the temperature signal over long distances. These signals frequently are used for process control purposes.

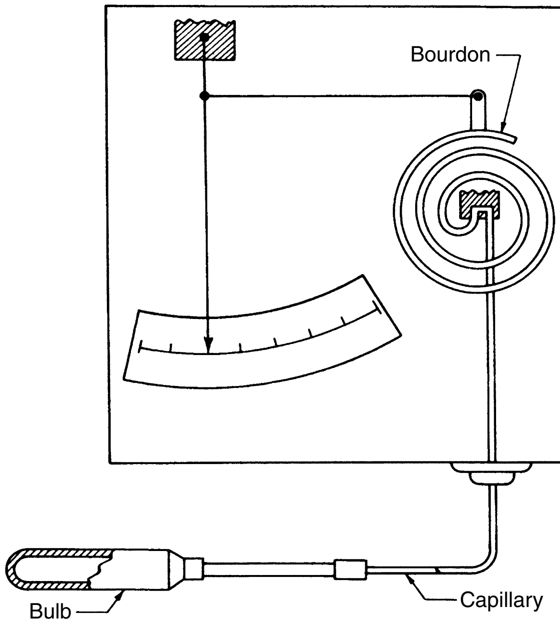

Fig. 1. Filled-system thermometer

Filled-system thermometers may be placed into one of two fundamental categories: (1) Those in which the bourdon responds to a volume change; and (2) those in which the bourdon responds to a *pressure change*. Those that respond to volume changes are completely filled with a liquid. The variation in liquid expansiveness with temperature is greater than that of the bulb metal, the net volume change being communicated to the bourdon. In this design, an internal-system pressure change is not of primary importance. In those systems that respond to pressure changes, the bulb is either filled with a gas, or partially filled with a volatile liquid. Changes in gas or vapor pressure with changes in bulb temperature are communicated to the bourdon. The bourdon will increase in volume with increase in pressure, but in this design, this effect is not of primary importance.

In liquid-filled thermal systems, mercury or various organic fills are used. In vapor-filled systems, a number of hydrocarbons, including ethane, ethyl chloride, ethyl ether, chlorobenzene, and propane, among others, are used. Nitrogen or other fully-dried and purified gases may be used in a gas thermometer.

THERMONUCLEAR FUSION REACTORS. See **Lithium**; **Nuclear Power Technology**.

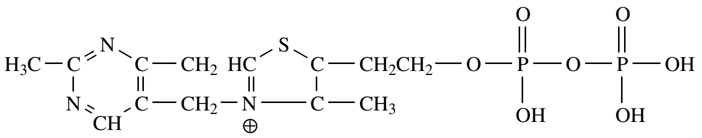
THERMOPLASTIC. A high polymer that softens when exposed to heat and returns to its original condition when cooled to room temperature. Natural substances that exhibit this behavior are crude rubber and a number of waxes; however, the term is usually applied to synthetics such as polyvinyl chloride, nylons, fluorocarbons, linear polyethylene, polyurethane prepolymer, polystyrene, polypropylene, and cellulosic and acrylic resins.

See also **Plastics**.

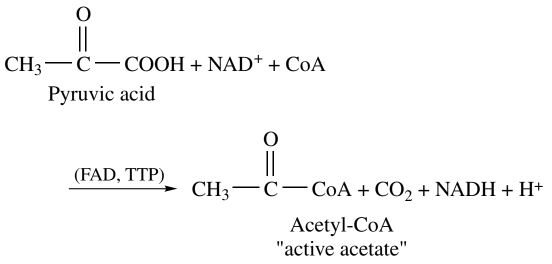
THERMOSET. A high polymer that solidifies or "sets" irreversibly when heated. This property is usually associated with a cross-linking reaction of the molecular constituents induced by heat or radiation, as with proteins, and in the baking of dough. In many cases, it is necessary to add "curing" agents such as organic peroxides or (in the case of rubber) sulfur. For example, linear polyethylene can be cross-linked to a thermosetting material by either radiation or chemical reaction. Phenolics, alkyds, amino resins, polyesters, epoxides, and silicones are usually considered to be thermosetting, but the term also applies to materials in which additive-induced cross-linking is possible, e.g., natural-rubber.

THERMOSETTING RESINS. See **Plastics**.

THIAMINE (Vitamin B$_1$). Some earlier designations for this substance included aneurin, antineuritic factor, antiberiberi factor, and oryzamin. Thiamine is metabolically active as thiamine pyrophosphate (TPP), the formula of which is:



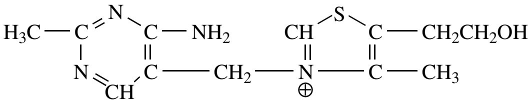
TPP functions as a coenzyme which participates in decarboxylation of α-keto acids. Dehydrogenation and decarboxylation must precede the formation of "active acetate" in the initial reaction of the TCA cycle (citric acid cycle):



This reaction is a good example of the interrelationship of vitamin B coenzymes. Four vitamin coenzymes are necessary for this one reaction: (1) thiamine (in TPP) for decarboxylation; (2) nicotinic acid in nicotinamide adenine dinucleotide (NAD); (3) riboflavin in flavin adenine dinucleotide (FAD); and (4) pantothenic acid in coenzyme A (CoA) for activation of the acetate fragment.

TPP also mediates the oxidative decarboxylation of α-ketoglutaric acid, another intermediate of carboxydrate metabolism in the citric acid cycle. The nutritional requirement for thiamine increases as dietary carbohydrate increases because of a greater demand for TPP.

The structure of thiamine hydrochloride is:



In this form and as other salts, such as thiamine mononitrate, the vitamin is available as a dietary supplement.

Diseases and disorders resulting from a deficiency of thiamine include beriberi, opisthotonos (in birds), polyneuritis, hyperesthesia, bradycardia, and edema. Rather than a specific disease, beriberi may be described as a clinical state resulting from a thiamine deficiency. In body cells, thiamine pyrophosphate is required for removing carbon dioxide from various substances, including pyruvic acid. Actually, this is accomplished by a decarboxylase of which thiamine pyrophosphate is a part. Where thiamine is deficient, the process of oxidation necessary for converting food into energy is impeded, causing a variety of manifestations throughout the body.

In so-called *dry* beriberi, pathologic alterations in neurons and nerve fibers occurs, leading in some instances to degeneration of peripheral nerves. This condition is termed peripheral neuritis, generally affecting the nerves in the arms and legs. There often is altered skin sensitivity to touch in the extremities and pain on pressure over large nerves. There is a gradual loss of muscle strength, which may lead to paralysis of a limb. In *wet* beriberi, there is a lessening of strength of the heart muscles. There is enlargement of the heart, dyspnoea, increased pulse rate, palpitation, and edema. Pathologically, degenerative changes are found in the nervous tissue, heart muscle, and gastrointestinal tract. In later stages, marked enlargement of the heart and liver may be noted.

In one form of thiamine deficiency, Wernicke's syndrome may be noted. Therein is paralysis, or weakness of the muscles that causes motion of the eyeball. Closely associated with thiamine deficiency are dietary problems of alcoholism. The psychotic disturbances of alcoholism, including delirium tremens, frequently respond to thiamine and other B complex vitamins. Injections of thiamine often produce dramatic improvements in persons suffering from beriberi. Beriberi sometimes occurs in infants who are breast-fed by mothers who suffer a thiamine deficiency. Beriberi remains of concern in the Orient where polished rice is a dietary staple.

In cattle, a thiamine deficiency causes podioencephalomalcia (PEM), characterized by blindness, decreased feed intake, incoordination, failure of rumen to contract, spasms, and paralysis. In swine, a deficiency retards growth and sometimes causes cyanosis (insufficient oxygen in blood), enlarged heart, accompanied by fatty degeneration of heart muscles. Chicks suffer from paralysis of peripheral nerves, causing polyneuritis (head drawn back).

Distribution and Sources

Relatively few natural foods are considered high in thiamine content.

High thiamine content (1,000–10,000 micrograms/100 grams). Ham, rice bran, soybean flour, wheat germ, yeast.

Medium thiamine content (100–1000 micrograms/100 grams). Almond, asparagus, barley, brazil nut, bean (kidney, lima, snap, soy, wax), beef, beet greens, broccoli, Brussels sprouts, carp, cashew, cauliflower, chicory, chestnut, chicken, clam, cod, corn (maize), dandelion greens, eggs, endive, gooseberry, groundnut (peanut), hazelnut, kale, kohlrabi, leek, lentil (dry), lobster, mackerel, milk, mushroom, oats, oyster, parsley, pea, pecan, plum, pork, potato, prune (dry), raisin (dry), rice (brown), salmon, turkey, veal, walnut, watercress.

Low thiamine content (10–100 micrograms/100 grams). Apple, apricot, artichoke, avocado, banana, beet, berry (black-, blue-, cran-, rasp-, straw-), cabbage, carrot, celery, cheeses, cherry, coconut, cucumber, currant, date (dry), eggplant, fig, flounder, grape, grapefruit, haddock, halibut, herring, lemon, lettuce, melons, orange, parsnip, peach, pear, pepper (sweet), pike, pineapple, prune, sardine, scallop, shrimp, tangerine, trout, tuna, turnip.

Commercial thiamine dietary supplements are prepared by synthesis: Pyrimidine + thiazole nuclei synthesized separately and then condensed; also build on pyrimidine with acetamidine. Precursors in the biosynthesis of thiamine include thiazole and pyrimidine pyrophosphate, with thiamine phosphate as an intermediate. In plants, production sites are found in grain and cereal germ.

Bioavailability of Thiamine

Factors which contribute to a lessening of thiamine bioavailability include: (1) cooking, inasmuch as the vitamin is heat labile and water soluble; (2) presence of certain enzymes in food, such as thiaminase for vitamin breakdown; (3) destruction by calcium carbonate, dibasic potassium phosphate, and manganous sulfate; (4) destruction by nitrites and sulfites; (5) diuresis and gastrointestinal diseases; and (6) presence of live yeasts and alkalis. An increase in availability can result from: (1) presence of cellulose in diet, which increases intestinal synthesis; (2) storage capacity in heart, liver, and kidney; and (3) stimulation of bacterial synthesis in intestine (normally none).

Antagonists of thiamine include pyrithiamine, oxythiamine, and 2-*n*-butyl homologue. Synergists include vitamins B$_2$, B$_6$, B$_{12}$, and niacin, pantothenic acid, and somatotrophin (growth hormone).

Unusual features of thiamine as observed by some researchers include: (1) it exerts a hormonal function in plants, controlling root growth; (2) it aids phosphorylation in liver, dephosphorylation in kidney; (3) it easily poisoned by heavy metals, acetyl iodide; (4) plant and animal cocarboxylases are identical; (5) it exerts a diuretic effect and it is constipating; (6) it can be allergenic on injection; (7) it is not available from intestinal bacteria; and (8) blood contains most cocarboxylase in leukocytes.

Thiamine is soluble in water and easily destroyed by heat. These two properties account for appreciable losses of thiamine from processed and stored foods. An acid medium favors the retention of thiamine, whereas an alkaline medium is detrimental to retention.

Determination of Thiamine

Bioassay methods include yeast fermentation; polyneuritic rate of cure in rat; bacterial metabolism. Physicochemical methods include thiochrome fluorescence; polarography; chromatography; absorption in neutral and acid solutions.

THIAZIDES. See **Diuretic Agents**.

THIN. A nontechnical word used by scientists with a variety of meanings. (1) In electronic metallurgy a thin film is a vapor-deposited coating having a thickness of only a single atom; such *monatomic* films, e.g., thorium on tungsten, are used in electronic devices such as cathodes. (2) A coating or film of fatty acid on water that is one molecule thick (about 200 Å) is called *monomolecular* film. (3) In thin-layer chromatography the term applies to a specially prepared mixture of adsorbents spread on a glass slide to a thickness of 1/100 inch. (4) The word is also used in the sense of a liquid of low viscosity, as in paint thinner and thin-boiling starch.

THIN FILMS. The term *thin films* is used for a wide variety of physical structures. Self-supporting solid sheets usually are called foils when thinned from thicker material by such methods as rolling, beating, or etching, and films when obtained by stripping a deposited layer from its substrate. Supported thin films are deposited on planar or (in special cases) curved substrates by such methods as vacuum evaporation, cathode sputtering, electroplating, electroless plating, spraying, and various chemical surface reactions in a controlled atmosphere or electrolyte. Thicknesses of such supported films range from less than an atomic monolayer to a few micrometers ($1\ \mu m = 10^{-4}$ centimeter). Thin films not forming a continuous sheet are called "island films." Particularly noble metals may condense as islands of considerable thickness (up to $\sim 10^2$ micrometer).

In scientific studies and technical applications, the use of well-controllable deposition methods such as vacuum evaporation and cathode sputtering are generally preferred. The film structure is markedly influenced by such deposition parameters as substrate composition and surface structure, source and substrate temperatures, deposition rate, and composition and pressure of the ambient atmosphere (where applicable). In general, the structure of films is more disordered than the corresponding bulk material. Smaller grains, higher dislocation concentrations, and deviations from stoichiometry are typical, and films approach bulk structure only as a limiting case. Under certain growth conditions, films exhibit preferential crystal orientations or even epitaxy. (Epitaxy means that the film structure is determined by the crystal structure and orientation of the underlying substrate.)

Solid thin films are common study objects in most phases of solid state physics. They supply the samples for the study of general structural and physical properties of solid matter where special beam methods require small quantities of material or extremely thin layers. For example, thin films are used in transmission electron microscopy and diffraction, neutron diffraction, ultraviolet spectroscopy, and X-ray diffraction and spectroscopy. Thin films represent the best means for studying physical effects, where these effects are caused by the extreme thinness of the material itself. Examples are the rotational switching of ferromagnetic films, electron tunneling phenomena, electromagnetic skin effects of various kinds, and certain optical interference phenomena. Films also are convenient vehicles for the investigation of nucleation and crystal growth, and for states of extremely disturbed thermodynamic equilibrium.

Presently, films find three major industrial uses: the decorative finishing of plastics, optical coatings of various kinds (mainly antireflection coatings, reflection increasing films, multilayer interference filters, and fluorescent coatings), and in electronic components.

Nucleation, Growth and Mechanical Properties of Films

In vacuum evaporation, molecules or atoms of thermal energy are deposited at a uniform angle of incidence and under well-defined environmental conditions. Most nucleation and growth studies, therefore, have been made on evaporated films. A particle approaching the substrate enters close to its surface a field of attracting short-range London forces with an exchange energy proportional to—$1/r^6$. At a still shorter distance r, repulsive forces proportional to $e^{-r/\text{constant}}$ resist the penetration of the electron clouds of the surface atoms. Due to the atomic or crystalline structure of the substrate, this potential field exhibits periodicity or quasiperiodicity in the substrate plane. The freshly condensed particles migrate over the surface with a jump frequency $i_D \propto \exp(-Q_D/kT)$, or desorb with a frequency $i_{ad} \propto \exp(-Q_{ad}/kT)$, where the activation energy Q_D is often approximately one-fourth of Q_{ad}. Permanent condensation occurs in most cases at distinct nucleation centers which may consist of deep potential wells of the substrate, clusters of condensed particles, or previously deposited "seed" particles of a different material. The number of nuclei formed in the second case is strongly temperature and rate dependent.

Most metals always condense in crystalline form, but the grain size is extremely small at low temperatures (in the order of a few micrometers) and increases markedly with increasing substrate temperatures. Grain size decreases with increasing deposition rates. The condensation of amorphous or quasi-liquid phases at low temperatures has been observed for such metals as antimony and bismuth and a few dielectrics. Some of these materials, on annealing, pass through otherwise unobserved and probably metastable phases.

Stresses of considerable magnitude are often observed in deposited films. The main causes of these stresses are a mismatch of expansion coefficients between substrate and film, enclosed impurity atoms, a high concentration of lattice defects and in very thin films, a variety of surface effects. Often, the stresses resulting from lattice defects can be minimized by the choice of a higher substrate temperature during deposition, or they can be reduced by a post-deposition anneal. Metal films frequently exhibit tensile strengths that are considerably larger than those of the corresponding bulk materials.

Thin-film Optics

Deposited metal mirrors probably represent the oldest optical application of films. High-quality mirrors usually are produced by the vacuum evaporation of aluminum on an appropriately shaped glass substrate. Often, a glow-discharge cleaning of the substrate or a chromium undercoat is first applied to increase the adhesion of the aluminum. After deposition, the aluminum is protected by anodic oxidation or an evaporated overcoat of SiO, SiO_2, or Al_2O_3.

For SiO, maximum reflectance in the visible spectral region is achieved at a thickness of about 1400 micrometers. Rapid SiO evaporation reduces the reflectance at shorter wavelengths.

Single or multilayer coatings find increasing use as optical interference filters. These film stacks may consist solely of transparent films of different refractive indices n_f, or a combination of absorbing and nonabsorbing layers. Common low-index materials for glass coatings in the visible region of the spectrum are MgF_2 ($n_f = 1.32$ to 1.37), and cryolite Na_3AlF_6 ($n_f = 1.28$ to 1.34); high-index materials are SiO ($n_f = 1.97$), ZnS ($n_f \approx 2.34$), TiO_2 ($n_f = 2.66$ to 2.69) and CeO_2 ($n_f = 2.2$ to 2.4). The indices are given for the sodium D-line. Various semiconductors are used for infrared coatings.

At each air-film, film-film, or film-substrate interface, the incident light amplitude is split into a reflected and a transmitted fraction according to the Fresnel coefficients

$$f_{j-1} = (\hat{N}_{j-1} - \hat{N}_j)/(\hat{N}_{j-1} + \hat{N}_j) \text{ and } g_{j-1} = 2\hat{N}_{j-1}/(\hat{N}_{j-1} + \hat{N}_j)$$

where j and $j-1$ denote the number of the optical layer counted from the side of the incident beam, $\hat{N}_j = N/\cos\Theta_j$ for p polarization or $\hat{N}_j = N_j/\cos\Theta_j$ for s polarization is the effective refractive index, and

$N_j = n_j - ik_j$ the refractive index of the j layer.

$$\cos\Theta_j = \sqrt{\left(\sqrt{p_j^2 + q_j^2} + p_j\right)/2} - i\sqrt{\left(\sqrt{p_j^2 + q_j^2} + p_j\right)/2}$$

$$p_j = 1 + (k_j^2 - n_j^2)[n_0 \sin\theta_0/(n_j^2 + k_j^2)]^2$$

$$q_j = -2n_j k_j [n_0 \sin\theta_0/(n_j^2 + k_j^2)]^2$$

The symbol θ_0 is the angle of incidence in the incident medium.

For nonabsorbing film stacks ($k_i = 0; i = 1, 2 \ldots, m+1$), the overall reflectance and transmittance may be obtained by summing the multiple coherent reflections between the film boundaries. A more general treatment based on electromagnetic theory yields for amplitude reflectance and transmittance the recursions formulas

$$r_{(j-1)-} = (f_{j-1} + r_{j-} \exp(-2i\hat{\Phi}_j))/(1 + f_{j-1} r_{j-} \exp(-2i\hat{\Phi}_j))$$

and

$$t_{(j-1)-} = (g_{j-1} t_{j-} \exp(-i\hat{\Phi}_j))/(1 + f_{j-1} r_{j-} \exp(-2i\hat{\Phi}_j))$$

$\hat{\Phi}_j = \Phi_j \cos\Theta_j$ is the effective phase thickness. $\Phi_j = (2\pi/\lambda)$. $N_j l_j$ where λ is the wavelength in vacuo, and l_j is the geometrical film thickness. The recursion is started on the side of emergence, using the initial conditions $r_{m-} = f_m$ and $t_{m-} = g_m$. Intensities are given by $R = |r_{0-}|^2$ and $T = (RN_{m+1}/n_0)|t_{0-}|^2$ where R denotes "real part of." If A_j is the absorption in the layer j, $R + T + \Sigma_j A_j = 1$.

A single antireflection coating of $\lambda/4$ optical thickness $n_f l_f$ yields zero reflectance at $n_{\mathrm{f}} = \sqrt{n_{\mathrm{glass}}}$. A double layer coating of $\lambda/4$ films requires $n_2/n_1 = \sqrt{n_{\mathrm{g}}}$. The transmission of a Fabry-Perot interference filter consisting of a dielectric spacer layer between two partially reflecting metal films is given by $I/I_0 = [(1 + A/T)^2 + (4R/T^2)\sin^2(\delta - 1)]^{-1}$ where $\Phi = 2\pi nl\cos\theta/\lambda$. R, T, and A are the reflection, transmission, and absorption coefficients of the reflecting layers. The refractive index and thickness of the spacer film are n and l. θ is the angle of refraction in the spacer, and δ the phase change for reflections at the spacer-metal film interfaces. $(I/I_0)_{\max} = (T/(1-R))^2$ and $(I/I_0)_{\min} = (T/(1+R))^2$. The band pass half-width is $\Delta\lambda_{1/2}; \lambda(1-R)/\mathrm{m}\pi R^{1/2}$ for the interference order $m(m\pi = \Phi)$. More complex coatings and filters, and their various applications, cannot be discussed here. It should be mentioned, however, that films play a very important role today in the accurate determination of the optical constants of many materials, but particularly of metals.

Thin-Film Electronics

Deposited dielectric film materials are SiO, MgF_2, ZnS, and various organic compounds. Thin capacitive layers in the 100 to 500 micrometers thickness region are often produced by the anodization of tantalum and aluminum to Ta_2O_5 or Al_2O_3, respectively. The breakdown strength and dielectric constant of films approach bulk values, but might be reduced by surface roughness, structural faults, and lower density. According to the Lorentz-Lorenz formula, the dielectric constant D changes with reduced density ρ as $dD/d\rho = 3C/(1 - C\rho)^2$, where C is a constant depending on the material. On metal-dielectric-metal films, quantum mechanical tunneling through the dielectric film becomes observable below a dielectric thickness of about 100 micrometers. For applied voltages less than the metal-insulator work function ϕ, the tunneling current density J is proportional to the applied voltage V, demonstrating that the low-voltage tunneling resistance is ohmic. $J = (qV/h^2 s) \times (2m^*\phi)^{1/2} \exp[-(4\pi s/h)(2m^*\phi)^{1/2}]$. At high applied voltages ($qV > \phi$), the current increases very rapidly:

$$J = (q^2 V^2/8\pi h\phi_s^2)\exp[-(8\pi s/3hqV)(2m^*)^{1/2}\phi^{3/2}].$$

s is the insulator thickness, m^* the electronic effective mass, and q the electron charge. Thicker dielectric films may exhibit in high fields appreciable Schottky or avalanche currents when they are greatly disordered.

Polycrystalline metal films generally show, due to their low structural order, a larger resistivity than the bulk material. According to Matthiessen's rule, the total resistivity can be expressed as $\rho = \rho(t) + \rho(i)$ where $\rho(t)$ is the temperature-dependent resistivity associated with scattering by lattice vibrations, and $\rho(i)$ is a temperature-independent resistivity caused by impurity or imperfection scattering. Very thin specimens with a thickness comparable to the electron mean free path show a $\rho(i)$ rapidly increasing with decreasing thickness. This increase is caused by an increasing contribution of non-specular electron scattering at the film surfaces. By annealing a metal film, $\rho(i)$ might be reduced permanently. A large $\rho(i)$ results in a small temperature coefficient α.

Many known superconductors can be deposited as superconductive films.

Through thin-film experiments, the energy gap in semiconductors can be measured, and material parameters, such as the penetration depth of magnetic fields, can be studied at dimensions less than the coherence range.

Studies of semiconductor films have shown many facets. The properties of epitaxial films have mainly been investigated on Ge and Si, and to a lesser degree on III–V compounds. Much work has been done on polycrystalline II–VI films, particularly with regard to the stoichiometry of the deposits, doping and post-deposition treatments, conductivity and carrier mobility, photo-conductance, fluorescence, electroluminescence, and metal-semiconductor junction properties. Among other semiconductors, selenium, tellurium, and a few transition metal oxides have found some interest.

Film resistors, capacitors, and interconnected R-C networks on planar glass or ceramic substrates are finding widespread industrial use. Common resistor materials are carbon, nichrome, and tin oxide in individual components; and nichrome, tantalum, tantalum nitride, SiO-chromium cermet, and cermet glazes in planar networks. Gold, copper, aluminum, or tantalum is used for termination lands, connection leads, and capacitor plates. SiO, MgF_2, and Ta_2O_5 serve as film capacitor dielectrics and crossover insulation. The geometrical configuration of the desired component or circuit pattern is obtained either by deposition through mechanical masks or by removing from a continuous sheet the undesired portions after the deposition process is completed. This removal is frequently accomplished by a combination of photolitho-graphic and etch processes.

The minimum length l and width w of a resistor are calculated from the given resistance R, the sheet resistance R in ohms per square, dissipated power P, and permissible power dissipation per square inch P by use of the formulas $w = \sqrt{(P \cdot R)/P \cdot R}$ and $l = wR/R$. The capacitance of film capacitors is given by $C = 0.225D(N-1)A/t$, where C is the capacitance in picofarads, D the dielectric constant, N the number of plates, A the area in square inches, and t the dielectric thickness in inches.

In retrospect, it is gratifying to note how much progress in thin-film electronics was made prior to a more penetrating and fundamental understanding of surface phenomena. It is only relatively recently that such experimental tools as angle-resolved photoelectron spectroscopy, synchrotron far-ultraviolet and X-ray spectroscopies, and back-scattering and channeling of energetic ions, have been used. New computational methods are now available for calculating detailed maps of the electron distribution at a surface. It has been found that the surface geometry is either a relaxed version of the bulk structure, or a reconstructed arrangement with symmetry wholly different from the bulk. A comparison of the electron spectroscopy results with theoretical predictions of surface state energy spectra based on a particular surface model allows confirmation of the assumed atomic arrangement. Together, the theoretical and experimental approaches have provided the first complete description of surfaces, including identification of the atomic species present, their atomic arrangement, and the distribution of valence electrons in space and energy. It is quite possible that these approaches will lead to a detailed picture at the atomic level of the interface structure, electron states, charges, reconstruction, and the related junction electronic properties of semiconductor-semiconductor and metal-semiconductor interfaces.

Various barrier layer diodes have exhibited impressive rectification ratios, but limited breakdown strength and low speed due to their large specific capacitance. Of the many film transistor concepts studied, the insulated gate field effect device has been promising. Its structure consists of a minute metal-dielectric-semiconductor capacitor. The semiconductor strip carries current between two terminals called source and drain. A field applied between metal "gate" and source modulates the semiconductor conductance and consequently the source-drain current. Usable semiconductor materials with a sufficiently low concentration of interface states are CdS, CdSe, and tellurium. These devices exhibit pentodelike characteristics with voltage gains ranging from 2.5 at 60 megahertz to 8.5 at 2.5 megahertz. The gain-bandwidth product GB, which is equal to the transconductance divided by 2π times the gate capacitance, reaches values of about 20 megahertz. It is determined by $GB = \mu_d V_D/2\pi L^2$, where μ_d is the effective drift mobility of the electrons, V_D the source-drain potential, and L the source-drain spacing, which is usually selected between 5 and 50 micrometers.

An outgrowth of prior thin-film technology and of basic surface science research has been molecular beam epitaxy—the MBE formation

of compound semiconductor films. The MBE technology involves the use of separate atomic and molecular beams from multiple thermal sources in high vacuum which irradiate a substrate at intensities selected to grow films having the desired composition and doping. The ability to achieve slow growth rates, together with independent control of the separate beam sources, permits the fabrication of semiconductor junction profiles, both in doping and in composition, with a precision approaching that of a single atomic layer. To date MBE has been used to prepare films and layer structures involving a number of GaAs and $Ga_xAl_{1-x}As$ devices. Included in such devices are varactor diodes having highly controlled hyperabrupt capacitance-voltage characteristics, IMPATT diodes, microwave mixer diodes, Schottky barrier field-effect transistors (FETs), injection lasers, optical waveguides, and integrated optical structures. Some authorities believe that the potential for MBE in solid-state electronics may be greatest for microwave and optical solid-state devices as well as for circuits where submicrometer layer structures are required. A recently demonstrated MBE GaAs Schottky barrier diode cryogenic mixer with a noise temperature of 315 K at 102 gigahertz is exemplary of the potential of MBE technology for millimeter wave electronics.

MBE superlattice structures also are very promising. These superlattice structures, with periodicities of 50–100 micrometers, show negative resistance characteristics attributed to resonant tunneling into the quantized energy states associated with the narrow potential wells formed by the layers. Detailed studies have shown that the potential well distributions may be controlled and positioned to a precision of a few atomic layers.

Thin-film technology has also played an important role in developing Josephson superconducting devices, which offer outstanding advantages in constructing ultrahigh-speed computers. These are tunnel-junction type devices.

Thin-film and surface phenomena are fundamental to the successful development, production, and use of solid-state devices. The research in this area is extensive. See also **Molecular and Supermolecular Electronics**.

Magnetic Films

Magnetic thin films of nickel-iron (usually deposited at an 80:20 composition by weight) exhibit a number of unusual properties, which have led to many experimental and theoretical studies, as well as to important applications in binary storage and switching, magnetic amplifiers, and magneto-optical Kerr-effect displays.

Such "Permalloy" films have two stable states of magnetization, corresponding to positive and negative remanence. When deposited in a magnetic field or at an oblique angle, they exhibit uniaxial anisotropy. In practice, this anisotropy shows some dispersion, since it results from the alignment of local lattice disturbances. The stable states result from the minimization of the free energy $E = MH_L \cos\theta - MH_T \sin\theta + K \sin^2\theta$, where the last term represents the anisotropy energy, and θ is the angle between the magnetization M and the easy axis. From an inspection of the derivatives of this equation follows the hard-direction straight-line and the easy-direction square hysteresis loops of aniso-tropic films. In the latter case, the magnetization is always either +M or −M, and the change occurs at $H_L = \pm H_K$. The transitions from unstable to stable states occur at $\partial^2 E/\partial\theta^2 = 0$, resulting in a critical curve $H_L^{2/3} + H_T^{2/3} = H_K^{2/3}$ which has the form of an asteroid enclosing the origin (see also **Magnetism**).

An important feature of magnetic films is the high speed with which the state of magnetization can be reversed. Dependent on film properties and magnetic fields, three modes of magnetization reversal occur: Domain wall motion, incoherent rotations, and the extremely fast coherent rotation of the magnetization. Wall motion switching is expected when the driving fields are smaller than the critical values. During the past decade, magnetic garnet films have gained prominence in a number of research and industrial applications.

THIN-LAYER CHROMATOGRAPHY (TLC). A micro type of chromatography. The thin layer (0.01 inch) is the adsorbent, usually a special silica gel spread on glass or incorporated in a plastic film. Single drops of the solutions to be investigated are placed along one edge of the glass plate, and this edge then dipped into a solvent. The solvent carries the constituents of the original test drops up the thin layer in a selective separation, so that a comparison with known standards and various identifying tests may be made on the spots formed.

See also **Thin**.

THINNER. A hydrocarbon (naphtha) or oleoresinous solvent (turpentine) used to reduce the viscosity of paints to appropriate working consistency usually just before application. In this sense, a thinner is a liquid diluent, except that it has active solvent power on the dissolved resin.

THIOALCOHOLS. See **Mercaptans**.

THIO- AND DITHIOCARBAMIC ACIDS. See **Herbicides**; **Insecticide**.

THIOCYANATES AND ISOTHIOCYANATES. See **Herbicides**; **Insecticide**.

THIOCYANIC ACID. [CAS: 463-56-9]. Aqueous solution of hydrogen thiocyanate, HSCN, formula weight 59.08, yellow solid below mp 5°C, unstable gas at room temperature. The acid is moderately stable only when dilute and cold. The salts of this acid are known as thiocyanates.

Thiocyanic acid is formed by reaction of barium thiocyanate solution and dilute sulfuric acid, and filtering off barium sulfate, or by the action of hydrogen sulfide on silver thiocyanate, filtering off silver sulfide.

Sodium, potassium, barium, or calcium thiocyanate may be made by reaction of sulfur and the corresponding cyanide by heating to fusion. Ammonium thiocyanate (plus ammonium sulfide) may be made by reaction of ammonia and carbon disulfide, a reaction which probably accounts for the presence of ammonium thiocyanate in the products of the destructive distillation of coal. This reaction corresponds to the formation of ammonium cyanate from ammonia and carbon dioxide.

Silver, lead, copper(I), and thallium(I) thiocyanates are insoluble and mercury(II), bismuth, and tin(II) thiocyanates slightly soluble. All of these are soluble in excess of soluble (e.g., ammonium) thiocyanate, forming complexes. Iron(III) thiocyanate gives a blood-red solution, used in detecting either Fe(III) or thiocyanate in solution, and is extracted from water by amyl alcohol. It is not formed in the presence of fluoride, phosphate and other strongly complexing ions.

When thiocyanic acid is treated with certain oxidizing agents, e.g., nitric acid, sulfuric acid and hydrocyanic acid are formed, but the action of lead tetraacetate on the acid, or of bromine in ether on lead(II) thiocyanate, gives thiocyanogen ("Rhodan") NCSSCN, a yellow, volatile oil, mp about −3°C, which polymerizes irreversibly at room temperature to insoluble, brick-red parathiocyanogen $(NCS)_x$. Thiocyanogen reacts with organic compounds like a free halogen. It liberates iodine from iodides. In water it is rapidly hydrolyzed to sulfuric and hydrocyanic acids. When thiocyanic acid is treated with reducing agents, e.g., aluminum and dilute hydrochloric acid, hydrogen sulfide plus carbon plus ammonium chloride are formed.

Esters

Ethyl thiocyanate $C_2H_5 \cdot SCN$, colorless liquid, bp 142°C. Formed by reaction (1) of potassium thiocyanate and potassium ethyl sulfate, (2) of cyanogen chloride and ethane-thiol. Oxidizable with fuming nitric acid to ethyl sulfonic acid $C_2H_5 \cdot SO_2OH$, and reducible with zinc and dilute sulfuric acid to ethane thiol C_2H_5SH. Ethyl isothiocyanate $C_2H_5 \cdot NCS$, colorless, odorous liquid, bp 132°C. Formed by reaction of ethyl amine and carbon disulfide (cf. the formation of ammonium thiocyanate from ammonia and carbon disulfide). Reducible to ethyl amine $C_2H_5NH_2$ plus methylene sulfide CH_2S. Allyl isothiocyanate ("mustard oil") $C_3H_5 \cdot NCS$ liquid, bp 151°C, odor of mustard, and causes blisters in contact with the skin.

THIOETHERS. Hydrogen sulfide yields two classes of organic compounds: (1) hydrosulfides, and (2) sulfides. The sulfides are termed thioethers. A more general term, *thiols*, also is used. This term not only embraces thioethers, but also covers thioalcohols, sulfhydrates, and thiophenols.

Ethyl sulfide $(C_2H_5)_2S$, one of the better known thioethers, is an odorous, inflammable liquid, mp −102.1°C, bp 91.6°C, sp gr 0.837. The compound is insoluble in H_2O and soluble in alcohol and ether. It is prepared by distilling ethyl potassium sulfate with potassium sulfide. Chemically, ethyl sulfide behaves much like the ethers. For example, none of the hydrogen atoms can be displaced by metals and generally the compound is very inert. Additional thioethers can be prepared in a similar manner with the corresponding proper ingredients. Upon oxidation with HNO_3, thioethers are converted to sulfones. The latter are stable crystalline substances. An example is ethyl sulfone $(C_2H_5)_2SO_2$.

THIOKOL RUBBERS. See **Elastomers**.

THIOPHENE. [CAS: 110-02-1]. ⟨$(CH{:}CH)_2$⟩S, formula weight 84.13, colorless liquid resembling benzene in odor, mp −30°C, bp 84°C, sp gr 1.070. Thiophene and its derivatives closely resemble benzene and its derivatives in physical and chemical properties. Thiophene is present in coal tar and is recovered in the benzene distillation fraction (up to about 0.5% of the benzene present). Its removal from benzene is accomplished by mixing with concentrated sulfuric acid, soluble thiophene sulfonic acid being formed. Thiophene gives a characteristic blue coloration with isatin in concentrated sulfuric acid.

Thiophene may be formed (1) by passing ethyl sulfide (diethyl sulfide) through a red-hot tube, (2) by reduction of sodium succinate and phosphorus trisulfide. Chlorine and bromine yield chloro- and bromo-substitution products, respectively, cold fuming nitric acid yields thiophene sulfonic acid. Thiophene aldehyde $C_4H_3S \cdot CHO$, liquid, bp 198°C, resembles benzaldehyde chemically rather than furfural. The corresponding primary alcohol and carboxylic acid are known. By comparison, where the sulfur atom of thiophene is occupied by oxygen, furane is the resulting compound. Where the sulfur atom of thiophene is occupied by a nitrogen group (NH), pyrrole is the resulting compound.

Benzothiophene $C_6H_4 \cdot (CH)_2S$ is a solid, mp 31°C, bp 221°C, with physical and chemical properties that resemble naphthalene. By comparison, where the sulfur atom of benzothiophene is occupied by oxygen, the resulting compound is benzofurane (coumarone). Where the sulfur atom of benzothiophene is occupied by a nitrogen group (NH), indole is the resulting compound.

THIOUREA. [CAS: 62-56-6]. $(NH_2)_2CS$, formula weight 76.12, white crystalline solid, mp 180–182°C, decomposes before boiling at atmospheric pressure, sp gr 1.405. Thiourea is moderately soluble in H_2O, soluble in alcohol, and slightly soluble in ether. Sometimes referred to as thiocarbamide, sulfurea, and sulfocarbamide, thiourea may be considered chemically analogous to urea and is oxidized to urea by cold potassium permanganate solution. The compound is easily hydrolyzed to NH_3, CO_2, and H_2S. Upon long heating below the melting point, thiourea is transformed to ammonium thiocyanate. Thiourea is attractive for plastics manufacture because of the greater ease with which substitution can be made on the sulfur atom of thiourea than on the oxygen atom of urea.

Thiourea is formed by heating ammonium thiocyanate at 170°C. After about an hour, 25% conversion is achieved. With HCl, thiourea forms thiourea hydrochloride; with mercuric oxide, thiourea forms a salt; and with silver chloride, it forms a complex salt.

Symmetrical diphenyl thiourea (thiocarbanilide) $(C_6H_5NH)_2CS$ is a solid, mp 154°C. When heated with concentrated HCl, the compound yields aniline plus phenylisocyanate. Formed by the reaction of aniline and CS_2, symmetrical diethylthiourea $(C_2H_5NH)_2CS$ is a solid, mp 77°C.

In addition to its use in plastics manufacture, thiourea is used in some photographic processes and photocopying papers; in organic synthesis as an intermediate (drugs, dyes, cosmetics); in rubber accelerators; and as a mold inhibitor.

THIXOTROPY. The ability of certain colloidal gels to liquefy when agitated (as by shaking or ultrasonic vibration) and to return to the gel form when at rest. This is observed in some clays, paints, and printing inks that flow freely on application of slight pressure, as by brushing or rolling. Suspensions of bentonite clay in water display this property, which is desirable in oil-well drilling fluids.

THOMSON, J. J. (1856–1940). Joseph John Thomson was an English physicist. At age fourteen, his father sent him to Owens College for preparatory scientific training. His attendance here was important to his career because this college had an outstanding science faculty and it also offered many experimental physics courses.

Thomson earned his engineering degree from Owens. Then he attended Trinity College of Cambridge University and studied mathematics and theoretical physics. When he graduated he began working in the Cavendish Laboratory at Cambridge and by age twenty-seven became its director. Thomson's main research was on the conduction of electricity through gases. After, Roentgen's discovery of X-rays in 1895, Thomson started working with Rutherford and found that passing X-rays through gases greatly increased their ability to conduct electricity. Much of Thomson's further research dealt with the composition of cathode rays. He believed that cathode rays were streams of tiny charged particles. His work concluded that the atom was not the fundamental unit of matter. He devised a model of the atom incorporating his theory of *corpuscles*. Later, the name "electron" was adopted.

In 1906, Thomson received the Nobel Prize for Physics "in recognition of the great merits of his theoretical and experimental investigations on the conduction of electricity by gases." Between the years of 1906 and 1914, Thomson studied canal rays and worked on separating the different kinds of atoms and atomic groupings present in them. In 1903, Thomson proposed a discontinuous theory of light, with light rays being composed of separate particles rather than continuous streams, and later Einstein developed the photon theory of light.

Thomson's work revolutionized scientific understanding of the atom and ushered in a new era in physical science. He is also remembered for his excellent teaching at Cavendish Laboratory.

See also **Electron Theory**.

J.M.I.

THOMSON PARABOLA METHOD. The method of investigating the charge-to-mass ratio of positive ions in which the ions are acted upon by electric and magnetic fields applied in the same direction normal to the path of the ions. It can be shown that ions of a given charge-to-mass ratio but different velocities will be deflected so as to form a parabola.

THOMSON PRINCIPLE. The hypothesis that, if thermodynamically reversible and irreversible processes take place simultaneously in a system, the laws of thermodynamics may be applied to the reversible process while ignoring for this purpose the creation of entropy due to the irreversible process. Applied originally by Thomson to the case of

thermoelectric effects. Also used in the treatment of electrochemical cells, thermal diffusion.

THORIANITE. This mineral of thorium oxide, ThO_2, is isomorphous with uraninite and occurs in black, nearly opaque cubic crystals in Ceylon and in Madagascar. Often containing rare-earth metals and uranium, the ore is strongly radioactive. Because of its radioactivity, it is valuable in helping to date the relative ages of rocks in which it occurs.

THORITE. The mineral thorite is a silicate of the rare element thorium and corresponds to the formula $ThSiO_4$. It is tetragonal and exhibits a prismatic cleavage. The original thorite was black in color with a specific gravity of 4.4–4.8. A variety orangite, so called from its orange-yellow color, has a specific gravity of 5.19–5.40. It has been found partly altered to thorite. Uranothorite contains uranium oxide. Thorite occurs in Norway in augite syenites. Thorite and orangite occur in Sweden, and orangite and uranothorite are found in Madagascar. Uranothorite is found in Ontario.

THORIUM. [CAS: 7440-29-1]. Chemical element symbol Th, at. no. 90, at. wt. 232.038, radioactive metal of the Actinide Series, mp 1750°C, bp 4790°C, density 11.5–11.9 g/cm^3 (17°C). Thorium metal is dark gray, dissolves in HCl, is made passive in HNO_3, and is not affected by fusion with alkalis. The element combines with chlorine or sulfur at 450°C; with hydrogen or nitrogen at 650°C. All thorium-containing substances are radioactive. The element was discovered by J.J. Berzelius in 1829. The electronic configuration

$$1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}4f^{14}5s^25p^65d^{10}6s^26p^66d^27s^2.$$

Ionic radii Th^{3+} 1.08 Å, Th^{4+} 0.95 Å (Zachariasen). Metallic radius 1.797_5 Å. First ionization potential 5.7 eV; second, 16.2 eV; third, 29.4 eV. Oxidation potentials $Th \longrightarrow Th^{4+} + 4e^-$, 1.90 V; $Th + 4OH^- \longrightarrow ThO_2 + 2H_2O + 4e^-$, 2.48 V. See also **Chemical Elements**.

The isotopes of thorium include mass numbers 223–234. ^{232}Th has a half-life of 1.39×10^{10} years. See also **Radioactivity**. It emits an alpha-particle and forms meso-thorium 1 (radium-228), which is also radioactive, having a half-life of 6.7 years, emitting a beta-particle. Since ^{232}Th captures slow neutrons to form, by a series of nuclear reactions, ^{233}U which is fissionable, thorium can be used as a fuel for nuclear reactors of the breeder type. Thorium occurs in earth minerals, an average content estimated at about 12 ppm. Findings of the *Apollo 11* space flight indicated that thorium concentrations in some lunar rocks are about the same as the concentrations in terrestrial basalts.

Thorium occurs in monazite sand in Brazil, India, North and South Carolina; this ore contains 3–9% thorium oxide, and is the chief source; thorium is also found in thorite containing about 60% oxide and in thorianite, about 80% oxide. When heated with concentrated H_2SO_4 the minerals form thorium sulfate, from which, by a series of reactions, thorium nitrate, the chief commercial compound, is obtained.

Thorium has the oxidation state of (IV) in all of its important compounds. Its oxide, ThO_2, and its hydroxide are entirely basic. The nature of the ions present in a number of solutions of the soluble compounds is not known with certainty. Complex ions involving sulfate are suggested by the increased solubility of the sulfate in solutions of the acid sulfates. Similarly, other complex ions are suggested by the solubility of the carbonate in excess alkali carbonate and of the oxalate in ammonium oxalate. Such ready complex ion formation is consistent with the high positive charge of the thorium-(IV) ion.

Although the exact extent is not known accurately, hydrolysis of various salts is known to occur. Since the hydroxide is not precipitated it is assumed that the hydrolysis product is some ion on the form $Th(OH)_2{}^{++}$ or $ThOH^{3+}$. The solution chemistry of thorium is made more complicated because of the hydrolytic phenomena observed and the polynuclear complex ions that are formed at low acidities and higher thorium concentrations.

Studies of the complex ions formed by Th^{4+} with various complexing anions have given much information. For example, the equilibria and ionic species involved in the chloride complexing of aqueous thorium have been studied through the method of measuring the distribution between H_2O and benzene containing thenoyltrifluoroacetone. The conclusion: that there is successive complexing involving the species $ThCl^{3+}$, $ThCl_2{}^{2+}$, $ThCl_3{}^+$ and $ThCl_4$. Similarly, all the intermediate chelate complex ions between thorium and acetylacetone exist in aqueous solution of proper acidity.

Thorium dioxide (face-centered cubic structure) is very insoluble in H_2O, but dissolves in acids to yield salts.

Thorium forms one series of halides, another one of oxyhalides, and also a series of double or complex halides. In general, stability of these compounds toward heat decreases as the atomic weight of the halogen increases. These compounds are often isostructural with the corresponding compounds of other actinide elements in the (IV) oxidation state.

Thorium metal reacts with hydrogen at moderately elevated temperatures to yield two hydrides: (1) ThH_2, which has a pseudotetragonal body-centered unit containing two metal atoms, isomorphous or pseudoisomorphous with thorium carbide, zirconium hydride, and zirconium carbide, ThC_2, ZrH_2, and ZrC_2; and (2) a hydride of approximate composition $ThH_{3.75}$ or ThH_4, possessing a unique cubic structure unrelated to that of the parent metal.

Thorium sulfide, ThS_2, is obtained by the action of H_2S or sulfur on thorium metal. The oxysulfide, ThOS, has been obtained in several ways, one of which is by the action of CS_2 on thorium dioxide at elevated temperatures. At 800°C and under pressure, sulfur combines with thorium to yield compounds with approximately the formulas ThS, Th_2S_3, and Th_3S_7. The first two have semimetallic properties and may be employed as ceramics for use with highly electropositive metals, whereas the last appears to be a polysulfide.

Anhydrous thorium sulfate, $Th(SO_4)_2$, is obtained by the action of concentrated H_2SO_4 on thoria (ThO_2). A solution of this salt deposits crystals of $Th(SO_4)_2 \cdot 9H_2O$ at about 15°C, $Th(SO_4)_2 \cdot 8H_2O$ near 24°C, and $Th(SO_4)_2 \cdot 4H_2O$ around 45°C. At 100°C other hydrates change to $Th(SO_4)_2 \cdot 2H_2O$. In aqueous solution, the salt is considerably hydrolyzed to an oxysulfate—for instance, $ThOSO_4 \cdot H_2O$.

Thorium nitrate, CAS: 13823-29-5, $Th(NO_3)_4 \cdot 12H_2O$, is obtained by dissolving thorium hydroxide in HNO_3.

Thorium orthophosphate, $Th_3(PO_4)_4 \cdot 4H_2O$, is precipitated by adding a solution of sodium phosphate to an acidic solution of a thorium salt. Thorium pyrophosphate, $ThP_2O_7 \cdot 2H_2O$, precipitates when an acidic solution of thorium nitrate is treated with one of tetrasodium pyrophosphate.

Thorium has been used as a fuel for nuclear reactors since it is a fertile material for the generation of fissionable uranium-233. Some experts have estimated that the energy available from the world's reserves of thorium is greater than all of the remaining fossil fuels (coal and petroleum) and of all of the remaining uranium, combined. Thorium oxide is used for gas mantles. The oxide also helps to control grain size in tungsten filaments and strengthens nickel alloys (TD nickel). Thorium is also used as an alloying addition in magnesium technology and as a deoxidant for molybdenum, iron, and other metals. Several applications for thorium are found in electronic technology.

Thorium oxide has a high refractive index and low dispersion and thus finds use in high-quality camera and scientific instrument lenses. Thorium oxide also is used as a catalyst in the conversion of ammonia to nitric acid, in petroleum cracking, and in sulfuric acid production.

Handling

^{232}Th is sufficiently reactive to expose a photographic plate within a few hours. Thorium disintegrates with the production of thoron (^{220}radon). The latter is an alpha emitter and a radiation hazard. Areas where thorium is stored should be well ventilated and all precautions in the handling of thorium materials must be taken.

THORIUM OXIDE. See **Thorianite**.

THORIUM SERIES. See **Radioactivity**.

THREE-PHASE EQUILIBRIUM. For every pure, chemically stable substance there is a certain temperature and pressure at which it can exist in all three states or phases, solid, liquid, and vapor, each phase being in equilibrium with each of the others. At higher temperatures and pressures than those at this so-called "triple point," the liquid and vapor states may attain equilibrium; solid-vapor equilibrium is possible at lower temperatures and pressures; and solid liquid equilibrium can be obtained at higher pressures and at lower or higher temperatures according as the substance contracts or expands upon melting. These three equilibria may be represented by three temperature-pressure graphs, which converge at the triple point. Figure 1 illustrates the case of water.

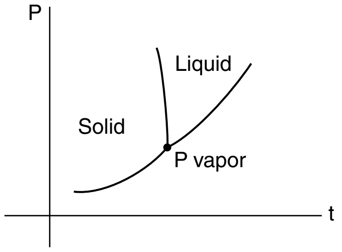

Fig. 1. Triple-point (P) on temperature-pressure diagram

In 1954, the thermodynamic temperature scale (i.e., the absolute Kelvin scale was redefined by setting the triple point temperature for water equal to exactly 273.16 K).

THREONINE. See **Amino Acids**.

THROMBIN. A proteolytic enzyme that catalyzes the conversion of fibrinogen to fibrin and thus is essential in the clotting mechanism of blood. It is present in the blood in the form of prothrombin under normal conditions; when bleeding begins, the prothrombin is converted to thrombin, which in turn activates the formation of fibrin.

THULIUM. [CAS: 7440-30-4]. Chemical element, symbol Tm, at. no. 69, at. wt. 168.934, twelfth in the Lanthanide Series in the periodic table, mp 1545°C, bp 1950°C, density 9.321 g/cm^3 (20°C). Elemental thulium has a close-packed hexagonal crystal structure at 25°C. The pure metallic thulium is gray in color, with no evidence of tarnishing up to a temperature of 200°C. Above 200°C, the element combines with oxygen, sulfur, nitrogen, carbon, and hydrogen and will form intermetallic compounds with most metals. At higher temperatures, halogen gases react vigorously with the element to form trihalides. There is one natural isotope of thulium ^{169}Tm. Seventeen artificial isotopes have been produced. Average content of the earth's crust is estimated at 0.48 ppm thulium, making this element the least abundant of the rare-earth elements. Even at this level, however, thulium is potentially more available than antimony, bismuth, cadmium, or mercury. The element was first identified by P.T. Cleve in 1879. Electronic configuration

$$1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}4f^{12}5s^25p^65d^16s^2.$$

Ionic radius Tm^{3+} 0.880 Å. Metallic radius 1.746 Å. First ionization potential 6.18 V; second 12.05 V. Other physical properties of thulium are given under **Rare-Earth Elements and Metals**.

Thulium occurs in apatite and xenotime and is derived from these minerals as a minor coproduct in the processing of yttrium. Processing involves organic ion-exchange, liquid-liquid, or solid-liquid, techniques. Prior to the development of cation exchange resins capable of separating the chemically similar rare earths, thulium was practically unavailable in pure form. Thulium metal is made by the direct reduction of thulium oxide by lanthanum metal at high temperature in a vacuum.

Important scientific and industrial applications for thulium and its compounds remain to be developed. In particular, the photoelectric, semiconductor, and thermoelectric properties of the element and compounds, particularly behavior in the near-infrared region of the spectrum, are being studied. Thulium has been used in phosphors, ferrite bubble devices, and catalysts. Irradiated thulium (^{169}Tm) is used in a portable x-ray unit.

Note: This entry was revised and updated by K. A. Gschneidner, Jr., Director, and B. Evans, Assistant Chemist, Rare-earth Information Center, Institute for Physical Research and Technology, Iowa State University, Ames, IA.

THYROID HORMONES. See **Hormones**; **Iodine (In Biological Systems)**.

TIN. [CAS: 7440-31-5]. Chemical element, symbol Sn, at. no. 50, at. wt. 118.69, periodic table group 4, mp 231.97°C, bp 2,270°C, density 7.29 g/cm^3 (white tin at 15°C), 5.77 (gray tin at 13°C), 6.97 (liquid at mp). There are two allotropic forms of tin: (1) the more common soft white beta tin has a body-centered tetragonal crystal form, (2) the brittle gray alpha tin has a diamond-type cubic crystal form. The cubic form, α-tin, stable below 18°C, is an intrinsic semiconductor, and is gray. At 161°C, white tin undergoes a transition to rhombic or γ-tin.

Tin is a silver-white metal with a bluish tinge, softer than zinc and harder than lead. It is malleable, ductile at 100°C; can be powdered at 200°C, and upon exposure to temperatures below 18°C, it crumbles to a grayish powder due to the "tin pest," which is caused by the transformation of white to gray tin (the reverse transformation may be brought about by heating gray tin to about 100°C). When a bar of tin is bent a marked creaking sound is emitted due to the friction of the crystals. Tin: is not oxidized on exposure to air at ordinary temperatures; burns to stannic oxide when heated to high temperatures in air or oxygen; is soluble in HCl to form stannous chloride; is converted by concentrated HNO_3 into soluble beta-stannic acid; is soluble in aqua regia to form stannic chloride; is soluble in NaOH solution slowly to form sodium stannite and hydrogen gas; and reacts with chlorine to form volatile stannic chloride. Discovery, prehistoric.

Tin has the largest number of naturally occurring isotopes ^{112}Sn, ^{114}Sn through ^{120}Sn, ^{122}Sn, and ^{124}Sn. Five radioactive isotopes have been identified ^{111}Sn, ^{113}Sn, ^{121}Sn, ^{123}Sn, and ^{125}Sn. With exception of ^{121}Sn, which has a half-life of about 5 years, the half-lives of the other isotopes are comparatively short, expressed in minutes and days. Tin occurs in the Earth's crust to the extent of about 40 grams/ton. It is estimated that a cubic mile of seawater contains about 15 tons of tin. First ionization potential 7.332 eV; second, 14.52 eV; third, 30.49 eV; fourth, 40.57 eV. Oxidation potential $Sn \longrightarrow Sn^{2+} + 2e^-$, 0.406 V; $Sn^{2+} \longrightarrow Sn^{4+} + 2e^-$, −0.14 V; $HSnO_2{}^- + 3OH^- + H_2O \longrightarrow Sn(OH)_6{}^{2-} + 2e^+$, 0.96 V; $Sn + 3OH^- \longrightarrow HSnO_2{}^- + H_2O + 2e^-$, 0.79 V. Electronic configuration $1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}5s^25p^2$.

Other important physical properties of tin are given under **Chemical Elements**.

Tin occurs as oxide (cassiterite, tin stone, stannic oxide, SnO_2), obtained commercially in Malaysia, Indonesia, Thailand, and Bolivia. The ore is concentrated and then roasted to oxide (83–88% stannic oxide). The product is treated in a blast furnace and crude tin recovered. Refining is conducted by electrolysis, or by fractional fusion.

Tin also occurs as complex sulfidic ores. The economic working of these ores is essentially confined to Bolivia. The ores include $SnS_2 \cdot Cu_2S \cdot FeS$ (stannite), SnS (herzenbergite, $SnS \cdot PbS$ (teallite), $2SnS_2 \cdot Sb_2S_3 \cdot 5PbS$ (franckeite), $Sn_6Pb_6Sb_2S_{11}$ (cylindrite), $2SnS_2 \cdot 2PbS \cdot 2(FeZn)S \cdot Sb_2S_3$ (plumbostannite), and $4Ag_2S \cdot SnS_2$ (canfieldite).

Secondary tin is an important source of the metal. Tinplate scrap may be detinned electrolytically or chemically. The alkaline chemical process is the most widely used and involves a caustic solution, which contains an oxidizing agent to remove both tin and the underlying iron-tin alloy

from the steel. The solution formed then is either (1) crystallized to form sodium stannate, (2) electrolyzed to recover tin metal, or (3) acidified with CO_2, H_2SO_4, or acidic gases to precipitate hydrated tin oxide. There are several secondary tin smelters in the United States, but only one primary smelter. The main primary tin smelters are located in the United Kingdom, Malaysia, and Thailand.

Uses. Not including former Soviet Bloc nations, world consumption of tin is in excess of 187,000 metric tons annually. Principal uses are: (1) tinplate, 35%; (2) solder, 24%; (3) bronze, 9%; (4) other alloys, 8%; (5) tinning, 4%; (6) chemicals, 5%; (7) other uses, 15%. In the United States, tin consumption in 1979 was: (1) tinplate, 29%; (2) solder, 29%; (3) bronze and brass, 14%; (4) chemicals, 8%; (5) other alloys, 9%; (6) tinning, 4%; (7) other uses, 7%. In the United States, the major portion of tinplate is used in the making of cans. The advantages of tin for cans and food-processing equipment include its nontoxic nature, resistance to corrosive attack by acids and other aqueous solutions, and when combined with other metals, strength.

Tin Plate. Tin coating may be applied to steel by (1) electroplating, usually as part of a high-speed, continuous process, or (2) by dipping cut sheets in a bath of molten tin. Electrolytic tin plate essentially is a sandwich in which the central core is strip steel. This core is thoroughly cleaned in a pickling solution prior to electroplating. The actual plating occurs as the strip moves through horizontal or vertical tanks containing electrolyte. The moving strip then is heated as it passes between high-frequency electric induction coils, whereupon the tin coating melts and flows to form a lustrous coat. The average thickness of tin on the end-product sheet is 0.00003 inch (0.0008 millimeter) on each side. A complex system of instrumentation is used to control process conditions and to inspect the moving sheet for any perforations in the plate. In hot-dip tinning, individual steel sheets are pickled and washed. A layer of hot palm oil is maintained on top of the molten tin bath to prevent oxidation of the molten tin by air and to prevent the molten tin from freezing too rapidly on the plate, thus providing a more even coating with a high luster.

Terne Plate. This is a sheet-steel product that is coated with an alloy of tin and lead. The coatings range from 50–50 mixtures of lead and tin to as low as 12% tin and 88% lead. Plate used for roofing normally is about 25% tin and 75% lead. In addition to roofing, terne plate is used in the manufacture of gasoline tanks for automotive vehicles, oil cans, and containers for solvents, resins, etc.

Tin-bearing solders are considered soft solders as contrasted with the hard solders which contain substantial quantities of silver. However, small quantities of silver are added to some tin solders to increase strength of the resulting joint and to adjust working temperature range. Antimony also is added in some cases for the latter purpose. Wiping solders usually have a tin content ranging from 35 to 40%. Solders used in automotive-body work require a wide plastic (working temperature) range. Solders with a low tin content (below 25%) are generally used. For very low-temperature melting, bismuth and cadmium also may be added to tin-lead solders.

Alloys. Tin is widely used as both a major and minor ingredient of alloy metals. These applications are summarized in Tables 1, 2, and 3. Phosphor bronzes (Table 3) actually contain very little phosphorus, ranging from 0.03 to 0.50%, and hence the alloys are poorly designated. Tin bronzes is the better term. High-silicon bronzes contain about 2.8% tin; low-silicon bronzes about 2.0% tin. Gun metals are tin bronze casting alloys with a 5–10% zinc content. Some wrought copper-base alloys contain tin: (1) Inhibited Admiralty metal, 1% tin; (2) manganese bronze, 1% tin; (3) naval brass, 0.75% tin, (4) leaded naval brass, 0.75% tin. See also **Copper**.

Copper-nickel-tin alloys (UNS C72500, 2700, and 2900) are *spinodal*[1] materials that can be age hardened after forming. They combine tensile strengths as high as 1380 MPa (200×10^3 psi) with resistance to oxidation, stress relaxation, fatigue, and stress-corrosion cracking. For use in round-wire form, these alloys are challenging the traditional position held by phosphor bronzes for electronic leads, contact pins, and sockets.

[a] Society of Automotive Engineers.

In flatwire form, they compete with beryllium copper for eyeglass frames, circuit boards, and electronic-contact clips. The alloys also have been used for rivets, self-threading screws, and a variety of cold-headed parts.

Chemistry and Compounds

Tin forms two series of compounds: tin(II) or stannous compounds and tin(IV) or stannic compounds. Tin(II) oxide, SnO, insoluble in water, is formed by precipitation of an SnO hydrate from an $SnCl_2$ solution with alkali and later treatment in water (near the boiling point and at constant pH). It is amphiprotic, but only slightly acid, forming stannites slowly with strong alkalis. Sodium stannite is conveniently prepared from tin(II) chloride: $SnCl_2 + 3NaOH \longrightarrow Na[Sn(OH)_3] + 2NaCl$. Tin(IV) oxide, SnO_2, is much more acidic; it readily reacts with NaOH to form stannate ions, $Sn(OH)_6{}^{2-}$. In fact, no hydroxide of the formula $Sn(OH)_4$ has ever been obtained. The metal metastannates, e.g., M^{II} SnO_3, are generally made by fusion methods and have three-dimensional polymeric anions in which each tin atom is surrounded octahedrally by six oxygen atoms. There are, however, two forms of stannic acid, H_2SnO_3. The α-stannic acid is a white, gelatinous precipitate obtained by treating $SnCl_4$ with NH_4OH. The α-stannic acid (also called metastannic acid) is a white powder obtained by action of concentrated HNO_3 on tin; unlike the α-form it is insoluble in concentrated acids and alkali metal hydroxides.

Tin forms dihalides and tetrahalides with all of the common halogens. These compounds may be prepared by direct combination of the elements, the tetrahalides being favored. Like the halides of the lower main group 4 elements, all are essentially covalent. Their hydrolysis requires, therefore, an initial step consisting of the coordinative addition of two molecules of water, followed by the loss of one molecule of HX, the process being repeated until the end product $H_2Sn(OH)_6$ is obtained. The most significant commercial tin halides are stannous chloride, stannic chloride, and stannous fluoride.

The increasingly electropositive character of main group 4 as tin is reached is evident from the fact that its hydrides are much less stable than

[1] Spinodal structure is a fine homogeneous mixture of two phases that form by the growth of composition waves in a solid solution during suitable heat treatment. The phases of a spinodal differ in composition from each other and from the parent phase, but have the same crystal structure as the parent phase.

those of silicon and germanium. Known are Sn_2H_6 and SnH_4, which is obtained by hydrolysis of magnesium stannide, Mg_2Sn, or by electrolysis of a phosphoric acid solution with a tin cathode.

Among the other inorganic compounds of tin are the:

Nitrates. Stannous nitrate $Sn(NO_3)_2$, white solid, by reaction of tin metal and dilute HNO_3 and crystallization, soluble in water with slight excess of HNO_3.

Sulfates. [CAS: 7488-55-3], Stannous sulfate, a white powder soluble in water and H_2SO_4, is obtained commercially by action of H_2SO_4 on $SnCl_4$ or Sn. Stannic sulfate may be formed by the solution of stannic hydroxide in dilute H_2SO_4, or by action of oxidizing agents on stannous salts.

Sulfides. Stannous sulfide SnS, dark brown precipitate, by reaction of stannous salt solution and H_2S, insoluble in sodium sulfide solution but soluble in sodium polysulfide solution, forming sodium thiostannate; stannic sulfide SnS_2, yellow precipitate, by reaction of stannic salt solution and H_2S, soluble in sodium sulfide solution, forming sodium thiostannate.

Organometallic Compounds

In common with the other elements of main group 4, tin forms many organometallic compounds; the range of possible combinations is virtually limitless. They include:

(1) *Tetraorganotins*, R_4Sn, prepared either by alkylation of tin halides with Grignard Reagents or alkyl lithium; by reaction of an organic halide with a tin-sodium alloy; by direct reaction of tin with an organic halide; or by reaction of stannic chloride with alkyl aluminum compounds.
(2) *Organotin halides*, $RSnX_3$, R_2SnX_2, and R_3SnX, prepared by disproportionation of the tetraorganotin with stannic halide or by direct alkylation of stannic halide.
(3) *Organotin oxides*, R_2SnO or $(R_3Sn)_2O$, prepared by treatment of the organotin halides with alkali.
(4) *Stannoic acids*, RSnOOH.

The organotin halides and oxides are usually the intermediates used in the synthesis of other organotin derivatives, such as the organotin carboxylates, organotin sulfur-derivatives, organotin hydroxides, etc. The most significant commercial organotins include dibutyltin and dioctyltin carboxylates and sulfur derivatives, used as polyvinyl chloride (PVC) stabilizers and as catalysts in polymer systems; *bis*(tributyltin)oxide, triphenyltin fluoride, and tributyltin fluoride, used as antifoulants for marine paints, fungicides, bactericides, sanitizing agents, and wood preservatives; tricyclohexyltin hydroxide as an insecticide; triphenyltin hydroxide and triphenyltin acetate as agricultural fungicides; and dibutyltin dilaurate as a poultry anthelmintic.

Biochemical Aspects of Tin

Scientists at the University of Maryland have found that sediment microflora (from Chesapeake Bay sediments) can produce dimethyltin and trimethyltin species from inorganic Sn(IV) compounds. The results were consistent with a geocycle of tin proposed by Ridley et al. in 1977. The findings support the hypothesis that tin can be biotransformed in an estuarine environment.

Researchers J. Versieck and L. Vanballenberghe (University Hospital, Ghent, Belgium) have observed, "Tin has chemical properties offering potentials for a biological function. The element has a tendency to form truly covalent linkages as well as coordination complexes; hence, it was hypothesized that it could well contribute to the tertiary structure of proteins or other biologically important macromolecules, such as nucleic acids. The oxidation-reduction potential of $Sn^{2+} \rightleftharpoons Sn^{4+}$ being at 0.13 V, well within the range of physiological oxidation-reduction reactions, it was also speculated that the element could function as the active site of metalloenzymes."

During the late 1960s, several experiments led to the conclusion that tin was indispensable for the growth of rats fed purified amino acid diets in trace-element-controlled isolators. However, no additional evidence for biological essentiality has been added since that time. Information on the tin content of foods is meager. Estimates have shown that the intake is less than 1 milligram per day. However, because of contamination from packaging, it has been estimated that this figure occasionally could rise to 50 mg/day. The aforementioned researchers have developed what appears to be a reliable method for determining tin in human blood serum by radiochemical neutron activation analysis.

TISELIUS, ARNE W. K. (1902–1971). A Swedish biochemist who won the Nobel prize for chemistry in 1948, for his research on electrophoresis and adsorption analysis, especially for his discoveries concerning the complex nature of the serum proteins. His work also involved virus isolation and synthesis of blood plasma. He earned degrees from the University of Uppsala and Princeton University, as well as a multitude of honorary degrees.

TISHCHENKO REACTION. Formation of esters from aldehydes by an oxidation-reduction process in the presence of aluminum or sodium alkoxides.

TITANITE. A yellow or brown calcium silicotitanite, $CaTiSiO_5$, having a waxy luster, and often containing niobium (columbium), chromium, fluorine, and other elements. Titanite occurs in wedge-shaped monoclinic crystals, usually as an accessory mineral in granitic rocks and in calcium-rich metamorphic rocks. See also **Sphene**.

TITANIUM. [CAS: 7440-32-6]. Chemical element, symbol Ti, at. no. 22, at. wt. 47.9, periodic table group 4, mp 1650–1670°C, bp 3,287°C, density 4.507 g/cm^3 (20°C). Below 885°C, elemental titanium has a hexagonal closepacked crystal structure; above this temperature, it has a body-centered cubic crystal structure. Compact titanium is a white metal, when cold it is brittle and may be powdered, but at red heat may be forged and drawn into wire. Titanium exhibits some passivity in air due to formation of coatings of oxide or nitride. At 610°C, titanium reacts with oxygen to form titanium dioxide; at 800°C, it reacts with nitrogen to form titanium nitride. Upon heating with chlorine, the metal forms titanium tetrachloride. Cold, dilute H_2SO_4 readily dissolves the metal to form titanous sulfate. Hot, concentrated H_2SO_4 yields titanic sulfate. The element was first identified by Gregor in 1789 and later named titanium by Klaproth (1795). A metal of 95% purity was not produced until 1887 when it was made by the reduction of titanium tetrachloride with sodium. The first commercial uses date back to 1860 when ferrotitanium was used as an alloying element in steel and a bit later as a deoxidizer in the production of steel. There are five natural isotopes of the metal ^{46}Ti through ^{50}Ti, and three radioactive isotopes have been identified ^{44}Ti, ^{45}Ti, and ^{51}Ti, the latter two with relatively short half-lives measured in minutes and hours. ^{44}Ti has a half-life of approximately 10^3 years. Titanium is relatively abundant, ranking 8th in the list of chemical elements occurring in the Earth's crust. Titanium ranks 35th among the elements in terms of content in seawater, with an estimated 5 tons of titanium per cubic mile (1.1 kilograms per cubic kilometer) of seawater. First ionization potential 6.83 eV; second, 13.60 eV; third, 27.6 eV; fourth, 44.66 eV. Oxidation potential $Ti + 2H_2O \longrightarrow TiO_2 + 4H^+ + 4e^-$, 0.95 V; $Ti \longrightarrow Ti^2 + 2e^-$, 1.75 V; $Ti^{2+} \longrightarrow Ti^{3+} + e^-$, 0.37 V. Electronic configuration $1s^22s^22p^63s^23p^63d^24s^2$.

Other physical properties of titanium are given under **Chemical Elements**.

Titanium occurs in practically all rocks and is an important constituent of many minerals. Only rutile TiO_2, however, is of commercial importance. The most important sources of this mineral are the sand dunes of Australia and Florida. Presently, Australia furnishes over 80% of the rutile requirements. Projects are underway to beneficiate (reduce) the other major potential titanium source, e.g., ilmenite. The known reserves of ilmenite $FeTiO_3$ are estimated 50 × greater than those of rutile. For mining the sand deposits for rutile, large floating dredge concentrators are used. Gravity concentration, followed by magnetic and electrostatic separation, yield a raw rutile of about 95% TiO_2 content. See also **Ilmenite**; and **Rutile**.

Production of titanium metal first involves the preparation of $TiCl_4$, a colorless liquid. Rutile and coke are charged into a continuous chlorinator. Upon the addition of chlorine gas, $TiCl_4$ is yielded in an exothermic reaction. To separate the metal, the $TiCl_4$, in a separate process, is reacted with molten magnesium metal pigs at about 50°C. The products are magnesium chloride $MgCl_2$ and titanium metal sponge. The by-product $MgCl_2$ is electrolyzed and the resulting magnesium and chlorine are recycled in the process. In another process, sodium metal is used instead of magnesium. And in still another process, the $TiCl_4$ may be electrolyzed.

Uses

The major uses for titanium are in various alloys, although unalloyed titanium finds some application. Titanium alloys are classified as alpha, alpha-beta, or beta, determined by the phases present in the alloy at room temperature. The alpha alloys usually result when the main elements present are the alpha stabilizers, e.g., oxygen, nitrogen, hydrogen, and carbon. Alpha-beta alloys and beta alloys contain increasing amounts of beta stabilizers, mainly vanadium, molybdenum, iron, chromium, manganese, tantalum, and niobium (columbium). The alpha-beta class of alloys normally has great room-temperature strength and may be heat treated. The annealed beta alloys show poor thermal stability over about 230°C, but do have good formability and weldability. The beta alloys may be age heat treated wherein some alpha phase is precipitated and this results in a very high room-temperature strength. The complexity of titanium alloys is brought about by the fact that the element is allotropic and undergoes a phase transformation at about 885°C, changing from one crystalline form to another as mentioned at the start of this entry. The variations in strength and percent elongation for the three major types of alloys and for pure titanium are given in Table 1.

Many diversified applications have been found for titanium and its alloys. Moreover, the number of these applications tends to increase steadily as greater production and improved processes reduce costs. At the present time, titanium is still an expensive material and is only used where its light weight, high strength, and corrosion resistance justify its cost. Aeronautical and missile design engineers find titanium and its alloys to be materials whose light weight and high strength, particularly at elevated temperatures (600°C), give them many applications in aircraft and missile construction. About 99% of all titanium materials are used in these fields.

Titanium and its alloys are widely used in compressor blades, turbine disks and many other forged parts of the jet engine. Here they offer resistance to high temperature, as well as weight-saving. The latter quality is increasing their use in the structural airplane parts, ranging from engines and air frames to skin and fastenings. Titanium sheet finds application in shroud assemblies, cable shrouds and ammunition tracks. Titanium alloy sheet is formed into ribs for use as stiffeners, as well as fuselage frames and bulk heads. Other uses of titanium in aircraft include channel sections, flat rubbing strips, landing gear doors, hydraulic lines, baffles, tail cones, longerons, etc. Other uses of titanium alloys include bulk heads, ducts, fire walls, etc.

The light weight of titanium and its alloys, coupled with their corrosion resistance, has brought them into use in ships, especially naval ships. Here many investigations show the important advantages of the metal and its alloys as wet exhaust muffles for submarine diesel engines, and as meter disks, and heat exchanger tubes which offer improved service for widespread use in salt water. Military applications of titanium extend from cannon and guided missiles to light-weight armor-plate for tanks. These materials offer other weight savings in other parts of military vehicles, such

TABLE 1. TITANIUM ALLOYS

Classification of alloys by application:

Airframe Alloys

Ti-75A, Ti-SAl-2.5Sn, Ti-6Al-6V-2Sn, Ti-6Al-4 V, Ti-7Al-4Mo, Ti-4Al-3Mo-IV, Ti-8Mn, Ti-13V-11Cr-3Al

Engine Alloys

Ti-8Al-1Mo-IV, Ti-SAl-2.5Sn, Ti-6Al-4V, Ti-6Al-2Sn-4Zr-2Mo, Ti-6Al-2Sn-4Zr-6Mo

Corrosion-Resistant Alloys

Ti-35A, Ti-50A, Ti-65A, Ti-0.2Pd, Ti-2Ni

as piston rods and transmissions, which may extend to the transportation industries generally.

Throughout the chemical industry, titanium is used extensively both in plant and in laboratory. Among important present-day applications are heat exchangers, autoclave heads, autoclave coils for cooling and heating, chemical processing racks, and valves and tanks where corrosion resistance is necessary.

Advancements in Titanium Technology

Increasingly, titanium alloys are competing with nickel-base alloys on the basis of cost, strength, and corrosion resistance. The alloy Ti-3Al-2.5 V, for example, is finding expanded use in the process industries because of its resistance to mildly reducing chloride environments.

Authorities in the field do not believe that the demand for titanium in the aerospace industry will be adversely affected by the increasing use of polymer-matrix composites in airframes and engines. Titanium has been replaced outright by composite materials in only a few aerospace applications. In those instances, the primary considerations have been weight reduction and "stealth" characteristics. By contrast, titanium has been selected instead of composites for several applications where the primary considerations have been titanium's superior stiffness and toughness as well as its multidirectional strength characteristics. Titanium also has gained favor because of its compatibility with composites. An example of this compatibility is found in titanium-aluminide foils. These are used to fabricate honeycomb structures. Fiber-reinforced alpha 2 titanium aluminide-matrix composites are fabricated by consolidating a foil/fiber/foil layup, using hot isostatic processing. The reinforcements are carbon-coated silicon-carbide continuous fibers.

Near-Net-Shape Processing

Even greater use of titanium in aircraft has been limited because of its relatively high cost (as compared with aluminum, by a factor of $10\times$ to $20\times$) and also because of its lower machinability. Gains are being made by titanium on both of these counts, however, by initially making titanium parts very close to the shape and dimensions of the desired end product (near-net-shape or NNS). These gains have been made through advanced titanium processing techniques and include precision casting, hot isostatic pressing, blended elemental (BE) powder techniques, and precision forging.

Increasingly, titanium alloys are competing with nickel-based alloys on the basis of cost, strength, and corrosion resistance.

Titanium Diboride

TiB_2 cermet is an extremely hard material. For several years, there was no successful process for depositing the material on parts for achieving wear resistance. A process was introduced by Montreal Carbide Co. in 1990, however, that deposits microspheres of TiB_2 in a metallic matrix. Using a conventional plasma-spray technique, a series of cermet coatings, in which the ceramic phase is finely and uniformly dispersed, yields a wear-resistant surface. TiB_2 is synthesized during spraying by a reaction between powders of titanium-bearing alloys and boron-bearing alloys. Due to the rapid solidification, the TiB_2 crystals that form are finely dispersed in a metallic matrix, which originated from the alloys used in the process.

Chemistry and Compounds

Due to its $3d^24s^2$ electron configuration, titanium forms tetravalent compounds readily, although the Ti^{4+} ion does not exist as such in aqueous solution, except at very low or high pH values, the common cation being hydrated TiO^{2+} (or more probably $Ti(OH)_2{}^{2+}$). Many of the tetravalent compounds are largely covalent. There are also Ti(III) and a few Ti(II) compounds, the latter being very easily oxidized. Titanium dioxide, TiO_2, is well known both as a mineral, of which three structural forms exist, and as an industrial product obtained from ferrous titanate, $FeTiO_3$ ores or by oxidation of tin(IV) chloride, $TiCl_4$. See also **Titanium Dioxide**. Moreover, the precipitate obtained by action of alkali metal hydroxides upon solutions of tetravalent titanium is a hydrated oxide. The latter is readily soluble in acids to form oxysalts, which are usually formulated in terms of the TiO^{2+} ion, without including its water of hydration, e.g., as $NaTiOPO_4$. The hydrated TiO^{2+} ion is not amphiprotic, in that it does not dissolve in alkali hydroxides. However, it does react on fusion with alkali carbonates to form such compounds as M_2TiO_3 and $M_2Ti_2O_5$, these compounds having been shown to be mixed oxides rather than titanates. The alkaline earth titanates have the face-centered perovskite structure, and barium titanate, widely used for its electrical properties, has been produced in other crystalline forms.

Lower oxides of titanium, Ti_2O_3 and TiO, have been produced by reduction of TiO_2.

All four of the common halogens form tetrahalides of titanium, $TiCI_4$ being a liquid at ordinary temperatures, while TiF_4, $TiBr_4$, and TiI_4 are solids. They are readily hydrolyzed, yielding as end products TiO_2 and the hydrogen halide, in the case of $TiCl_4$ an intermediate addition product of the type $H_2O \cdot TiCl_4$ is considered to be formed. This is in accordance with the behavior of $TiCl_4$ and $TiBr_4$ as Lewis acids to form such unstable adducts, not only with water, but with oxygen-function organic compounds. Likewise, titanium chelates are formed with oxygen donor compounds such as acetylacetone.

The dihalides of titanium, formed by reduction of the tetrahalides, are vigorous reducing agents and unstable; $TiCl_2$ is inflammable in air. The trihalides, though more stable than the dihalides, are effective reducing agents. Ti(III) occurs in aqueous solutions as $Ti(H_2O)_6{}^{3+}$.

Normal oxyacid salts of titanium are unknown, but many basic salts, formulated as stated above, in terms of TiO^{2+}, though more or less hydrated, have been prepared.

Like the oxide, halides and sulfide, the nitride, boride, and carbide of titanium(IV) can be made by heating the elements together at high temperatures. The last three compounds are alloy-like in character, they can vary in composition without becoming unstable and they are extremely hard.

The halogen complexes are the most stable complex ions of titanium. The hexafluorotitanate ion, $TiF_6{}^{2-}$ is very stable, as are the peroxo-complexes, containing $-Ti-O-O-$. The $TiCl_6{}^{2-}$ and $TiBr_6{}^{2-}$ complexes are less stable, except in concentrated solutions of the hydrogen halides. A number of compounds of the $TiCl_5{}^{2-}$ ion are known, especially of the higher alkali metals, e.g., $M_2TiCl_5 \cdot H_2O$.

TITANIUM DIOXIDE. [CAS: 13463-67-7]. TiO_2, formula weight 79.90, variously colored, depending upon source, but white when purified and sold in commerce. Decomposes at about 1,640°C before melting, density 4.26 g/cm^3, insoluble in H_2O, soluble in H_2SO_4 or alkalis. Titanium dioxide is a very high-tonnage material and is the principal white pigment of commerce. The compound has an exceptionally high refractive index, great inertness, and a negligible color, all qualities that make it close to an ideal white pigment. Annual production approximates two million metric tons, of which nearly one-half of this amount is produced in the United States. Major uses of TiO_2 pigments are: (1) paint, 60%, (2) paper, 14%, (3) plastics and floor coverings, 12%, (4) printing inks, 3%, and (5) various applications including rubber, ceramics, roofing granules, and textiles, 11%.

Two major processes are used for producing raw titanium dioxide pigment: (1) the sulfate process, a batch process accounting for over half of current production, introduced by European makers in the early 1930s; and (2) the chloride process, a continuous process, introduced in the late 1950s and accounting for most of the new plant construction since the mid-1960s. The sulfate process can handle both rutile and anatase, but the chloride process is limited to rutile.

In the sulfate process, ilmenite (45–60% TiO_2) or a slag rich in titanium (70% TiO_2) obtained from electric smelting of ilmenite, is the feedstock. The raw materials first are digested: $FeTiO_3 + 2H_2SO_4 \longrightarrow FeSO_4 + TiO \cdot SO_4 + 2H_2O$. In a second step, the concentrated liquor is nucleated, diluted with H_2O, and boiled until nearly all of the titanium has precipitated out in the form of flocculated titanium dioxide (anatase) hydrate: $TiO \cdot SO_4 + 2H_2O \longrightarrow TiO_2 \cdot H_2O + H_2SO_4$. After filtering, the cake is leached under reducing conditions to remove residual iron. Conditioning agents are added, after which the hydrate is dried and calcined in a rotary kiln at approximately 900°C: $TiO_2 \cdot H_2O \longrightarrow TiO_2 + H_2O$. The conditioning agents usually consist of a phosphate and a potassium salt, as well as zinc, antimony, and aluminum compounds. The purpose of these additions is to improve the final properties of the pigment, including color, photochemical stability, and dispersibility, as well as to catalyze the formation of rutile from the anatase hydrate.

In the chloride process, the feedstock must be high in titanium and low in iron. Mineral rutile (95% TiO_2) is best suited, but leucoxene (65% TiO_2) can be used. See also **Brookite**. An economical conversion of ilmenite for use as a chloride process feedstock has not been developed to date. The ore is mixed with coke and chlorinated at about 900°C in a fluidized bed. The principal product is titanium tetrachloride, but other impurities including iron also are chlorinated and thus must be removed by selective condensation and distillation. Up to this point, the process is similar to that of producing titanium metal as described under **Titanium**. By selective reduction prior to distillation, vanadium present is removed as $VOCl_3$. In the next step, the purified $TiCl_4$ reacts with oxygen at a temperature of about 1,000°C. The presence of $AlCl_3$ in this reaction promotes the formation of rutile instead of anatase. The two major steps are: (1) chlorination: $3TiO_2 + 4C + 6Cl_2 \longrightarrow 3TiCl_4 + 2CO + 2CO_2$; and (2) oxidation: $TiCl_4 + O_2 \longrightarrow TiO_2 + 2Cl_2$. The chlorine is recycled. The raw titanium dioxide product generally is neutralized by washing in an aqueous solution of proper pH.

Many grades of titanium dioxide pigments are offered commercially. They range in crystal structure (anatase or rutile), particle shape and size, the type of hydrous oxide coating applied, and the type and quantity of additives applied. Generally, the commercial pigments contain 80–99% TiO_2, the remainder of the formulation comprised of alumina and silica hydrates. Nonpigmentary grades of titanium dioxide for the glass, welding-rod, electroceramic, and vitreous-enamel industries contain 99% TiO_2.

TITRATION (Potentiometric). This analytical method is based in principle upon the Nernst equation, which may be written in the form

$$E = E^0 - \frac{0.059}{n} \log \frac{A_{ox}}{A_{red}}$$

where E is the measured electromotive force, E^0 is the standard value of the electromotive force (electrode potential) when the substances of the electrochemical reaction are in their standard states, n is the valence change (change in number of electrons per mole of the reactants) and the A-terms are the activities of the oxidized and reduced forms of the reactants. See also **Activity Coefficient**. Activities are proportional to concentrations, so that the concentration of one of the reactants may be determined if that of the other is known. Thus the concentration of Cu^{2+} ions in a solution could be found by use of an electrode of metallic copper (unstrained metals are assumed to be at unit activity). Or the concentration of Cl^- ions in a solution could be found by use of an electrode of (insoluble) silver chloride AgCl deposited on an electrode of metallic silver. Or the concentrations in a solution containing two ions in different states of oxidation, such as Fe^{2+} and Fe^{3+}, could be found by the use of an inert electrode, such as one of platinum. The three reactions and corresponding forms of Nernst's equation (using the approximation of substituting concentrations for activities) are:

$$Cu^0 \Longleftrightarrow Cu^{2+} + 2e^-$$

$$E = E^0 - \frac{0.0591}{2} \log c_{Cu^{2+}}$$

$$Ag^+ + Cl^- \Longleftrightarrow AgCl \downarrow$$

$$E = E^0 - (0.0591) \log K_{sp} + (0.0591) \log c_{Cl-}$$

(where K_{sp} is the solubility product of AgCl)

$$Fe^{2+} \Longleftrightarrow Fe^{3+} + e^-$$

$$E = E^0 - (0.0591) \log \frac{c_{Fe^{3+}}}{c_{Fe^{2+}}}$$

In constructing an electric cell for potentiometric titrations it is necessary, of course, to use a second electrode to complete the circuit, in addition to the measuring electrodes (commonly called *indicator electrodes*) described above. Ideally the second electrode would be a hydrogen electrode which (as explained in the entry on electrode potential) is the standard reference electrode for which the potential, in equilibrium with its ions, is defined as zero. Since it is awkward to use, other electrodes of known potential, such as the calomel electrode or the glass electrode, are commonly used as reference electrodes. The arrangement of the apparatus is as shown in Fig. 1.

The procedure in a potentiometric titration is to determine the potential of the indicator electrode after each addition of the titrating solution. This is done by closing the switch in the circuit shown in Fig. 1 just long enough to read the potential on the sensitive measuring device used, such as a potentiometer or vacuum tube voltmeter. Of course, very small additions of titrant are made as the expected endpoint is approached. Then the readings of potential are plotted against volume of titrant added, as shown in Fig. 2. Reactions suitable for determination by this method show sharply defined endpoints as pictured in the figure. To correspond to the true stoichiometric endpoint, certain conditions should be met, including reversibility of the reaction and allowing time for the electrodes to reach

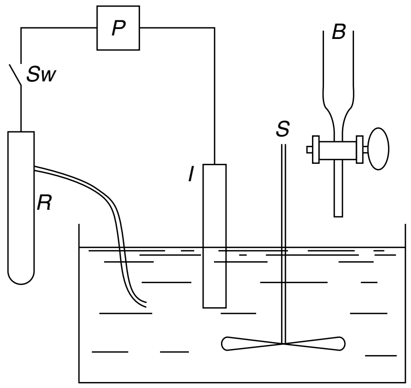

Fig. 1. Apparatus for potentiometric titration: (R) reference electrode; (I) indicating electrode; (P) potentiometer; (B) burette; (S) stirrer; (Sw) switch

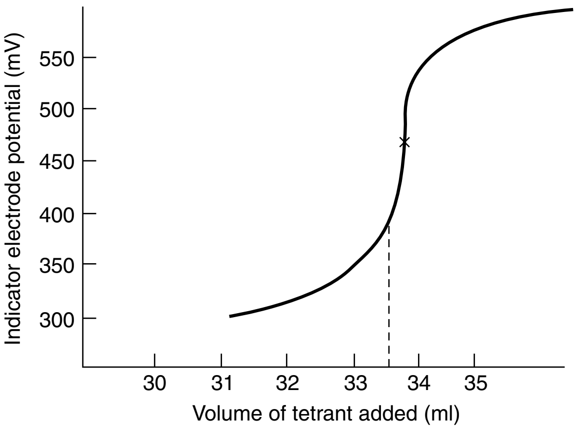

Fig. 2. Potentiometric titration curve

equilibrium before closing the switch to read the potential difference. While the description given was on the basis of titration with zero current drawn from the electrodes between readings, there is also a method in which a small constant current is drawn, not large enough to affect their potentials, but serving to eliminate some of the sources of error in the null method.

Types of titrations for which potentiometric methods of determining endpoints are particularly useful including titrations of halide mixtures, of various metals, of alkaloids, in non-aqueous solvents, and various titrations with oxidizing agents, such as permanganate, dichromate, iodate, and ceric sulfate.

TITRATION (Thermometric). This technique consists of the detection and measurement of the change in temperature of a solution as the titrant is added to it, under as near adiabatic conditions as possible. Experimentally, the titrant is added from a constant-delivery burette into the titrate (solution to be titrated) which is contained in an insulated container such as a Dewar flask. The resultant temperature-volume (or time) curve thus obtained is similar to other titration curves, e.g., acid-base, in that the end point of the reaction can be readily ascertained. Since all reactions involve a detectable endothermic or exothermic enthalpy change, the technique has potentially wide application in analytical chemistry, especially in those cases where other more common methods are not applicable.

Several idealized thermometric titration curves for an exothermic reaction are given in Fig. 1. A titration curve in which the titrant and the titrate are at the same initial temperature is illustrated in (a). The actual titration is preceded by a blank run, *CD*, in which no titrant is added to the titrate. At D, titrant is added, causing the temperature of the titrate to rise rapidly, reaching a maximum value at E. Beyond E, additional titrant causes no further change in the temperature of the titrate, hence, the horizontal excess reagent line, *EF*. The temperature rise of the titrate (and titration vessel), ΔT, is obtained by determining the vertical distance between the excess reagent line, ED', and *CD*. In curve (b), the conditions of the titration were identical to those of (a) except that the titrant was at a higher temperature than the titrate, hence, the sloping excess reagent line, *EF*. For curve (c), conditions were also identical to the above except that the titrant was at a lower temperature than the titrate. The excess reagent line, *EF*, thus slopes in an opposite direction to that of curve (b). For an endothermic reaction, the curves would be identical to the above except that the temperature changes would be in an opposite direction.

TOCOPHEROLS. See **Vitamin E**.

TODD, SIR ALEXANDER R. (1907–1997). A British chemist who won the Nobel prize for chemistry in 1957. His diverse research and accomplishments involved phosphorylation and mechanisms of biological reactions concerning phosphates. Many of his studies concerned the structure of nucleic acids, nucleotides, nucleotidic coenzymes, as well as vitamins B_1, B_{12}, and E. Work in biological organic chemistry indicated that hemp plant could be used for production of narcotics. Todd had degrees awarded from Oxford, Frankfurt, and Glasgow, among others.

TODOROKITES. Calcium-bearing manganese oxides found in terrestrial manganese ore depositions, in weathering products of manganese-bearing rocks, and in some manganese nodules. Todorokites are, in many instances, principal constituents of manganese nodules. Host copper and nickel within the modules is potentially of economic importance. Knowledge of todorokites is important for understanding how nodules form and how they concentrate transition elements from ocean waters. See **Ocean Resources (Mineral)**.

Formerly believed to be a single phase, todorokite was discredited as a mineral by the International Mineralogical Association Commission on New Minerals and Mineral Names in 1970 when evidence was submitted showing it to be a complex mixture of several compounds. As reported by Turner and Buseck (1981), many mineralogists felt the decision was incorrect since recognizable x-ray diffraction patterns could be produced from todorokite collected from widespread deposits. X-ray patterns have not been adequate for structure determination. Further confusion is caused by the variable morphology of todorokite, which appears fibrous in some samples and platy in others. Todorokite material appears to have a range of related structures. High-resolution transmission electron microscopy reveals that terrestrial todorokites consist of tunnel structures of previously unreported dimensions and that these tunnel structures are intergrown coherently on a unit cell scale. As shown in Fig. 1, many types and degrees of disorder are evident. The widespread presence of disorder explains prior confusion with x-ray diffraction patterns and hence the difficulty to relate x-rays studies with specific structures. Turner and Buseck suggested a revised

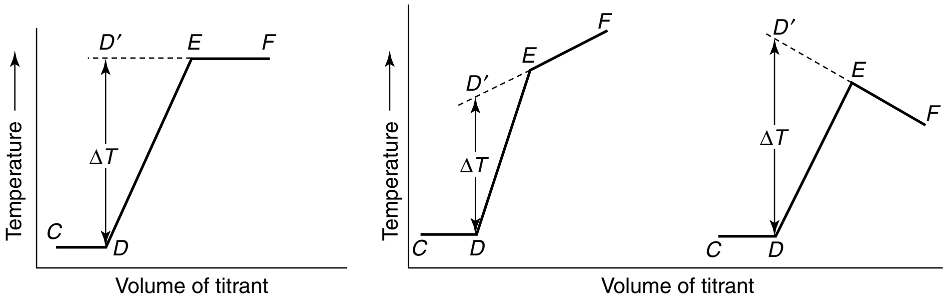

Fig. 1. Thermometric curves for an exothermic reaction (ideal)

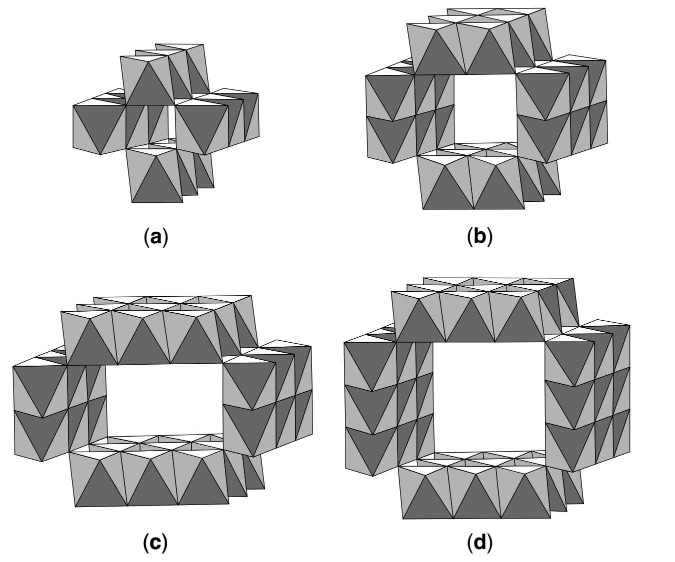

Fig. 1. Diagram of various manganese oxide tunnel structures. The common smallest unit of the structures is a [Mn^{+3}, Mn^{+4}]o_6 octahedron. The octahedra are edge linked to form long chains that are corner linked to form the framework of tunnel minerals: (**a**) 1 × 1, pyrolusite, (**b**) 2 × 2, hollandite, (**c**) 2 × 3, romanechite and (**d**) 3 × 3, todorokite. The larger tunnel structures (hollandite, romanechite, todorokite) can accommodate large cations and water. There are many more possible tunnel structures and those with a common dimension (for instance the double chain sides of hollandite and romanechite) can intergrow on a unit cell level. As far as is now known, todorokite occurs only as an intergrowth of differently sized tunnel structures that have a triple chain in common (3 × 2, 3 × 3, 3 × 5, 3 × 6, etc.) The 3 × 3 structure is the most prevalent. (*Source: S. Turner*)

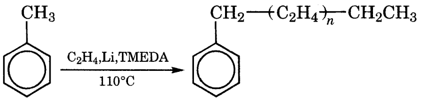
nomenclature of tunnel manganese oxides. This is described in *Science*, **212**, 1024–1027 (1981).

TOLUENE. Toluene, [CAS: 108-88-3], C_7H_8, is a colorless, mobile liquid with a distinctive aromatic odor somewhat milder than that of benzene. Prior to World War I, the main source of toluene was coke ovens. Petroleum became the source for toluene with the advent of catalytic reforming and the need for large quantities of toluene for use in aviation fuel during World War II. Since then, manufacture of toluene from petroleum sources has continued to increase, and manufacture from coke ovens and coaltar products has continued to decrease.

Toluene is generally produced along with benzene, xylenes, and C_9-aromatics by the catalytic reforming of C_6–C_9 naphthas. There have been, ca 1997, recent technological developments to produce benzene, toluene, and xylenes from pyrolysis of light hydrocarbons C_2–C_5, LPG, and naphthas. See also **Xylenes and Ethylbenzene**. About 85–90% of the toluene produced annually in the U.S. is not isolated, but is blended directly into the gasoline pool as a component of reformate and of pyrolysis gasoline.

Derivatives are formed by substitution of the hydrogen atoms of the methyl group, by substitution of the hydrogen atoms of the ring, and by addition to the double bonds. Substitutions on the methyl group are generally high-temperature, free-radical reactions. Thus, chlorination at ca 100°C, or in the presence of uv or other free-radical initiators, successively gives benzyl chloride, benzal chloride, and benzotrichloride. See also **Benzaldehyde**; and **Benzoic Acid**. With oxygen in the liquid phase, particularly in the presence of a catalyst, good yields of benzoic acid are obtained. In the presence of alkali metals, toluene is alkylated. With a lithium catalyst and a chelating compound, telomers are obtained with ethylene.

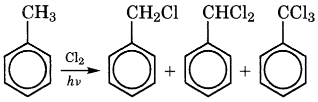


Additions to the double bonds results from both free-radical and catalytic reactions, e.g., chlorination at 0°C and hydrogenation. Usually, all three double bonds react. Substitution of the ring hydrogen atoms by electrophilic attack takes place with the same reagents that react with benzene. Some of the common groups with which toluene can be substituted directly include

$$—Cl,\ —Br,\ —\overset{O}{\overset{\|}{C}}CH_3,\ —SO_3H,\ —NO_2,\ —(C_nH_{2n+1}),\ \text{and}\ —CH_2Cl.$$

Under the same conditions, toluene reacts more rapidly than benzene. These reactivities and the related selectivity to the ortho and para positions can be explained in terms of the inductive effect of the methyl group. Toluene requires substitution by strongly negative groups, such as NO_2, to react with anions.

Substitution Reactions on the Methyl Group. The reactions that give substitution on the methyl group are generally high temperature and free-radical reactions. Thus, chlorination at ca 100°C, or in the presence of ultraviolet light and other free-radical initiators, successively gives benzyl chloride, benzal chloride, and benzotrichloride.



This oxidation reaction which yields benzoic acid is another example of this type of reaction.

In the presence of alkali metals such as potassium and sodium, toluene is alkylated with ethylene on the methyl group to yield, successively, normal propylbenzene, 3-phenylpentane, and 3-ethyl-3-phenylpentane.

In the formation of π-complexes with electrophiles such as silver ion, hydrogen chloride, and tetracyanoethylene, toluene differs from either benzene or the xylenes by a factor of less than two in relative basicity.

Properties

Physical and thermodynamic properties are given in Table 1. Toluene forms azeotropes with many hydrocarbons and most alcohols that boil in a similar range; all are minimum-boiling azeotropes. Toluene, water, and alcohols frequently form ternary azeotropes.

TABLE 1. PHYSICAL PROPERTIES OF TOLUENE

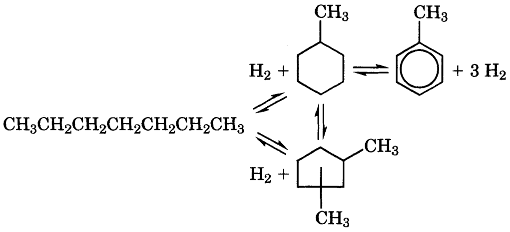
Property	Value
molecular weight	92.14
melting point, K	178.15
normal bp, K	383.75
critical temperature, K	591.80
critical pressure, MPa[a]	4.108
critical volume, L/(g · mol)	0.316
critical compressibility factor	0.264
acentric factor	0.262
flash point, K	278
autoignition temperature, K	809
GAS PROPERTIES, 298.15°K	
H_f, kJ/mol[b]	50.17
G_f, kJ/mol[b]	122.2
C_p, J/(mol · K)[b]	104.7
H_{vap}, kJ/mol[b]	38.26
H_{comb}, kJ/mol[b]	−3734
viscosity, mPa · s(= cP)	0.00698
flammability limits, in air[c], vol%	
lower limit at 1 atm	1.2
upper limit at 1 atm	7.1
LIQUID PROPERTIES, 298.15°K	
density, L/mol	9.38
C_p, J/(mol · K)[b]	156.5
viscosity, mPa · (= cP)	0.548
thermal conductivity, W/(m · K)	0.133
surface tension, mN · m(= dyn/cm)	27.9
SOLID PROPERTIES	
density at 93.15°K, L/mol	11.18
C_p at 178.1 K, J/(mol · K)[b]	90.0
heat of fusion at 178.15°K, kJ/mol[b]	6.62

[a] To convert MPa to psi, multiply by 145.
[b] To convert J to cal, divide by 4.184.
[c] At 101.3 kPa (1 atm).

Because of the high electron density in the aromatic ring, toluene behaves as a base both in the formation of charge-transfer π-complexes and in the formation of sigma complexes. When only π-electrons are involved, toluene behaves much like benzene and xylene. When σ-bonds and complexes are involved, toluene reacts much faster than benzene and much slower than xylenes.

Manufacture and Processing

The principal source of toluene is catalytic reforming of refinery streams. This source accounts for ca 79% of the total toluene produced. An additional 16% is separated from pyrolysis gasoline produced in steam crackers during the manufacture of ethylene and propylene. The reactions taking place in catalytic reforming to yield aromatics are dehydrogenation or aromatization of cyclohexanes, dehydroisomerization of substituted cyclopentanes, and the cyclodehydrogenation of paraffins. The formation of toluene by these reactions is shown.



Of the main reactions, aromatization takes place most readily and proceeds ca 7 times as fast as the dehydroisomerization reaction and ca 20 times as fast as the dehydrocyclization. Hence, feeds richest in cycloparaffins are most easily reformed.

Because catalytic reforming is an endothermic reaction, most reforming units comprise about three reactors with reheat furnaces in between to minimize kinetic and thermodynamic limitations caused by decreasing temperature. There are three basic types of operations, i.e., semiregenerative, cyclic, and continuous. In the semiregenerative operation, feedstocks and operating conditions are controlled so that the unit can be maintained on-stream from 6 mo-2 yr before shutdown and catalyst regeneration. In cyclic operation, a swing reactor is employed so that one reactor can be regenerated while the other three are in operation. Regeneration, which may be as frequent as every 24 h, permits continuous operation at high severity. Since ca 1970, continuous units have been used commercially. In this type of operation, the catalyst is continuously withdrawn, regenerated, and fed back to the system.

Toluene, Benzene, and BTX Recovery. The composition of aromatics centers on the C_7- and C_8-fraction, depending somewhat on the boiling range of the feedstock used. Most catalytic reformate is used directly in gasoline. That part which is converted to benzene, toluene, and xylenes for commercial sale is separated from the unreacted paraffins and cycloparaffins or naphthenes by liquid–liquid extraction or by extractive distillation.

Proper choice of feedstocks and use of relatively severe operating conditions in the reformers produce streams high enough in toluene to be directly usable for hydrodemethylation to benzene without the need for extraction. Toluene is recovered from pyrolysis gasoline, usually by mixing the pyrolysis gasoline with reformate and processing the mixture in a typical aromatics extraction unit. Yields of pyrolysis gasoline and the toluene content depend on the feedstock to the steam-cracking unit. Pyrolysis gasoline is hydrotreated to eliminate dienes and styrene before processing to recover aromatics.

Emerging Technologies for Production of BTX from Light Hydrocarbons. Recent technological developments have centered on high temperature pyrolysis of light hydrocarbons C_2 to C_5, LPG, and naphtha to form aromatics in higher yields. Conversions were traditionally low because they were accompanied by a high degree of degradation to carbon and hydrogen. Recent improvements include modification of the thermal cracking process to produce higher yields of liquid products rich in aromatics and the extension of the catalytic hydroforming process to promote oligomerization and dehydrocyclization of the lower olefins. The common core of these developments is the use of shape-selective zeolite catalysts to promote the various reactions.

Specifications, Standards, and Quality Control

Toluene is marketed mostly as nitration and industrial grades. The generally accepted quality standards for the grades are given by ASTM D841 and D362, respectively.

Purity of toluene samples as well as the number, concentration, and identity of other components can be readily determined using standard gas chromatography techniques.

Health and Safety Factors

Permissible exposure limits established by the U.S. Department of Health and Human Services and the U.S. Department of Labor are summarized below, with the more restrictive levels proposed by NIOSH.

	OSHA, mg/m^3 (ppm)	NIOSH, mg/m^3 (ppm)
average during 8-h shift (TWA)	752 (200)	376 (100)
not to exceed	1129 (300)	
except for 10-min average (TLV)	1181 (500)	752 (200)

Toluene generally resembles benzene closely in its toxicological properties; however, it is devoid of benzene's chronic negative effects on blood formation.

Uses

About 90% of the toluene generated by catalytic reforming is blended into gasoline as a component of $>C_5$ reformate. The octane number $(R + M/2)$ of such reformates is typically in the range of 88.9–94.5, depending on severity of the reforming operation. Toluene itself has a blending octane number of 103–106, is exceeded only by oxygenated compounds such as methyl *tert*-butyl ether, ethanol, and methanol.

Toluene is a valuable blending component, particularly in unleaded premium gasolines. Although reformates are not extracted solely for the purpose of generating a high octane blending stock, the toluene that is co-produced when xylenes and benzene are extracted for use in chemicals, and that exceeds demands for use in chemicals, has a ready market as a blending component for gasoline.

Toluene is converted to benzene by hydrodemethylation either under thermal or catalytic conditions. Benzene produced from this source generally supplies 25–30% of the total benzene demand. The feedstock is usually extracted toluene, but some reformers are operated under sufficiently severe conditions or with selected feedstocks to provide toluene pure enough to be fed directly to the dealkylation unit without extraction.

Toluene is more important as a solvent than either benzene or xylene. Solvent use accounts for ca 14% of the total U.S. toluene demand for chemicals. About two-thirds of the solvent use is in paints and coatings; the remainder is in adhesives, inks, pharmaceuticals, and other formulated products utilizing a solvent carrier. Use of toluene as solvent in surface coatings has been declining, primarily because of various environmental and health regulations. It is being replaced by other solvents.

Potential Uses. Because much toluene is demethylated for use as benzene, considerable effort has been expended on developing processes in which toluene can be used in place of benzene to make directly from toluene the same products that are derived from benzene. Such processes both save the cost of demethylation and utilize the methyl group already on toluene. Most of this effort has been directed toward manufacture of styrene. An alternative approach is the manufacture of *para*-methylstyrene by selective ethylation of toluene, followed by dehydrogenation. Resins from this monomer are expected to displace polystyrene because of price and performance advantages.

Derivatives

Toluene Diisocyanate. Toluene diisocyanate is the basic raw material for production of flexible polyurethane foams. It is produced by the reaction in which toluene is dinitrated, the dinitrotoluene is hydrogenated to yield 2,4-diaminotoluene, and this diamine in turn is treated with phosgene to yield toluene 2,4-diisocyanate.

Benzoic Acid. Benzoic acid is manufactured from toluene by oxidation in the liquid phase using air and a cobalt catalyst. Typical conditions are 308–790 kPa (30–100 psi) and 130–160°C. The crude product is purified

by distillation, crystallization, or both. Yields are generally >90 mol%, and product purity is generally >99%.

Benzyl Chloride. Benzyl chloride is manufactured by high temperature free-radical chlorination of toluene. The yield of benzyl chloride is maximized by use of excess toluene in the feed. More than half of the benzyl chloride produced is converted by butyl benzyl phthalate by reaction with monosodium butyl phthalate. The remainder is hydrolyzed to benzyl alcohol, which is converted to aliphatic esters for use in soaps, perfume, and flavors. Benzyl salicylate is used as a sunscreen in lotions and creams.

Disproportionation to Benzene and Xylenes. With acidic catalysts, toluene can transfer a methyl group to a second molecule of toluene to yield one molecule of benzene and one molecule of mixed isomers of xylene. This disproportionation is an equilibrium reaction. Disproportionation generates benzene from toluene and at the same time takes full advantage of the methyl group to generate a valuable product, i.e., xylene. Economic utility of the process is strongly dependent on the relative values of toluene, benzene, and the xylenes.

Vinyltoluene. Vinyltoluene is used as a resin modifier in unsaturated polyester resins. Its manufacture is similar to that of styrene; toluene is alkylated with ethylene, and the resulting ethyltoluene is dehydrogenated to yield vinyltoluene.

Toluenesulfonic Acid. Toluene reacts readily with fuming sulfuric acid to yield toluene–sulfonic acid. By proper control of conditions, *p*-toluenesulfonic acid is obtained. The primary use is for conversion, by fusion with NaOH, to *p*-cresol. The resulting high purity *p*-cresol is then alkylated with isobutylene to produce 2,6-di-*tert*-butyl-*p*-cresol (BHT), which is used as an antioxidant in foods, gasoline, and rubber. Mixed cresols can be obtained by alkylation of phenol and by isolation from certain petroleum and coal–tar process streams.

Benzaldehyde. Annual production of benzaldehyde requires ca 6,500–10,000 t ($2-3 \times 10^6$ gal) of toluene. It is produced mainly as by product during oxidation of toluene to benzoic acid, but some is produced by hydrolysis of benzal chloride. The main use of benzaldehyde is as a chemical intermediate for production of fine chemicals used for food flavoring, pharmaceuticals, herbicides, and dyestuffs.

Toluenesulfonyl Chloride. Toluene reacts with chlorosulfonic acid to yield both *o*- and *p*-toluenesulfonyl chlorides. The ortho isomer is converted to saccharin. The para isomer is used for preparation of specialty chemicals. Annual toluene requirements are ca 6500 t (2×10^6 gal).

Miscellaneous Derivatives. Other derivatives of toluene, none of which is estimated to consume more than ca 3000 t (10^6 gal) of toluene annually, are mono- and dinitrotoluene hydrogenated to amines; benzotrichloride and chlorotoluene, both used as dye intermediates; *tert*-butylbenzoic acid from *tert*-butyltoluene, used as a resin modifier, dodecyltoluene converted to a benzyl quaternary ammonium salt for use as a germicide; and biphenyl, obtained as by-product during demethylation, used in specialty chemicals. Toluene is also used as a denaturant in specially denatured alcohol (SDA) formulas 2-B and 12-A.

TOPAZ. The mineral topaz is a silicate of aluminum and fluorine corresponding to the formula $Al_2SiO_4(F, OH)_2$. It is orthorhombic and its crystals are mostly prismatic terminated by pyramidal and other faces, the basal pinacoid being often present. Massive varieties are known. It has an easy and perfect basal cleavage, hence for this reason gems or fine specimens should be handled with care to avoid developing cleavage flaws. The fracture is conchoidal to uneven; hardness, 8; specific gravity, 3.4–3.6; luster, vitreous; color, of typical topaz, wine or straw-yellow but may be colorless, white, gray, green, blue or reddish-yellow; transparent to translucent. When heated, yellow topaz often becomes a reddish pink.

Topaz is found associated with the more acid rocks of the granite and rhyolite type and may occur with fluorite and cassiterite. Topaz comes from many localities, a few of which are: the former U.S.S.R. in the Urals and the Ilmen Mountains; the Czech Republic and Slovakia, Saxony, Norway, Sweden, Japan, Brazil and Mexico. In the United States, topaz has been found in Oxford County, Maine; Carroll County, New Hampshire; Fairfield County, Connecticut; El Paso and Chaffee Counties, Colorado; and in Texas, Utah and California.

The name *topaz* is derived from the Greek meaning to seek. It was the name of an island in the Red Sea that was difficult to find, and from which a yellow stone, now believed to be a yellowish-olivine, was obtained in ancient times. In the Middle Ages, any yellow stone was called topaz, but now the name is properly applied only to the species here described.

TOPOCHEMICAL REACTION. Any chemical reaction that is not expressible in stoichiometric relationships. Such reactions are characteristic of cellulose; they can take place only at certain sites on the molecule where reactive groups are available, i.e., in the amorphous areas or on the surfaces of the crystalline areas.

TORBERNITE. An ore of uranium with the composition, $Cu(UO_2)_2(PO_4)_2 \cdot 8-12H_2O$, green, radioactive, tetragonal, and isomorphous with autunite. Occurring in tabular crystals or in foliated form, the mineral is commonly a secondary mineral.

TOTH PROCESS. A process for production of aluminum metal that utilizes kaoliln and other high-alumina clays. The clay is chlorinated after calcination, and the aluminum chloride resulting is reacted with metallic manganese to yield aluminum and manganese chloride. The reaction occurs at the comparatively low temperature of 260°C. The manganese chloride is recovered as manganese metal and chlorine by oxidation and subsequent reduction, the manganese being recycled. This is a much cheaper and more efficient method than the Hall process, because it requires less energy input and does not utilize imported bauxite.

TOURMALINE. The mineral tourmaline is a complex silicate of aluminum and boron, but because of isomorphous replacements this mineral varies widely in chemical composition, iron, magnesium, and lithium entering into combination to a greater or less extent with the aluminum and boron. Its general formula is $(Na, Ca)(Mg, Fe^{2+}, Fe^{3+}, Al, Li)_3Al_6(BO_3)_3(Si_6O_{18})(OH, F)_4$. Tourmaline belongs to the hexagonal system, its crystals are usually prismatic, tending to be long and slender, often acicular. The crystals are ordinarily terminated with three faces of a rhombohedron and usually hemimorphic. The smaller crystals are frequently found in radial arrangement, and columnar masses are common. The prisms are usually three-, six-, or nine-sided with heavy vertical striations producing a rounded effect.

Tourmaline is essentially without cleavage; fracture, conchoidal to uneven; brittle; hardness, 7–7.5; specific gravity, 3.03–3.25; luster, vitreous inclining to resinous; color, in common tourmaline black, bluish-black, brown, blue, green, red or pink, and in the transparent varieties colorless (rare), various shades of rose and pink, greens, blues and browns. The color arrangement in tourmaline is of considerable interest; bicolored crystals are common and may be green at one end and pink at the other, or green on the outside, and pink within, which, in the case of transparent or translucent crystals, is very attractive.

The opaque black tourmaline is called schorl, a term which was applied to all tourmaline until 1703 when the word *tourmaline* was introduced, it being a corruption of the Ceylonese word, *turamali*. The origin of the word *schorl* is not known, but is perhaps Scandinavian, and is used to identify the iron-bearing black tourmalines; elbaites and liddicoatites tend to light shades of blue, red, green, and their bicolored combinations; the brown colored tourmalines of varying shades of dark brown to yellow to nearly colorless are called dravites and uvites (with the exception of the black tourmalines found at Pierrepont, New York, which have been identified as uvites); the completely colorless variety, achroite, falls within the elbaite group. Small tourmalines are found in granites and some gneisses.

Due to the mineralizing action of magmatic vapors, tourmaline is found particularly well developed in pegmatites, and as a contact metamorphic

mineral. A few of the important localities are: the Ural Mountains; Bohemia; Saxony; the Island of Elba; Norway; Devonshire and Cornwall, England; Greenland; Madagascar. Magnificent elbaite crystals are obtained from Madagascar, Brazil, and Afghanistan; liddicoatite crystals from Madagascar. In the United States in Oxford and Androscoggin Counties, Maine; Grafton and Sullivan Counties, New Hampshire; Hampshire County, Massachusetts; Haddam and Fairfield Counties, Connecticut; St. Lawrence County, New York; Sussex County, New Jersey; Delaware County, Pennsylvania; and San Diego County, California.

See also terms listed under **Mineralogy**.

TOWNSEND AVALANCHE. A term used in gas-filled counter technology to describe a process which is essentially a cascade multiplication of ions. In this process an ion produces another ion by collision, and the new and original ions produce still others by further collisions, resulting finally in an "avalanche" of ions (or electrons). The terms "cumulative ionization" and "cascade" are also used to describe this process. It occurs in a nonself-maintained gas discharge, where ions have sufficient energy.

TOXICITY. The ability of a substance to cause damage to living tissue, impairment of the central nervous system, severe illness, or, in extreme cases, death when ingested, inhaled, or absorbed by the skin. The amounts required to produce these results vary widely with the nature of the substance and time of exposure to it. "Acute" toxicity refers to exposure of short duration, i.e., a single brief exposure; "chronic" toxicity refers to exposure of long duration, i.e., repeated or prolonged exposures.

The toxicity hazard of a material may depend on its physical state and on its solubility in water and acids. Some metals that are harmless in solid or bulk form are quite toxic as fume, powder, or dust. Many substances that are intensely poisonous are actually beneficial when administered in micro amounts, as in prescription drugs, e.g., strychnine.

Toxicity is objectively evaluated on the basis of test dosages made on experimental animals under controlled conditions. Most important of these are LD_{50} (lethal dose, 50%) and the LC_{50} (lethal concentration, 50%) tests, which include exposure of the animal to oral ingestion and inhalation of the material under test. A substance having an LD_{50} of less than 400 mg/kg of body weight is considered very toxic.

TOXICOLOGY. The technology of poisonous substances—their detection, and counteractions. Basic to this branch of science is the realization that chemical compounds vary in their danger to humans and their environment. Poisons can be simple or complex, inorganic or organic chemical compounds, bacterial or viral byproducts (toxins), animal-produced substances, such as venom—all of which produce ill effects on humans ranging from a low level of debilitation to almost instant death. Drugs used in countering diseases or physiological deficiencies can, in some doses, act as poisons. Many metals or elements are essential for life, but their body concentration for optimum health varies from element to element and depends somewhat on bodily weight. Once these optimum concentrations are exceeded, the metals or elements become contaminating, polluting, and often harmful.

Levels of toxicity ratings range from unknown, through low or light toxicity to moderate and severe. Exposure may also be acute, sub-acute, or chronic. Dusts, fumes, mists, vapors, gases or liquids may be absorbed through the skin, orally, or through the lungs. See also **Toxicity**.

Sources of information pertaining to toxic substances include local and national health organizations in many countries. Several treatises on the subject have been prepared, including the broad spectrum "Sax's Dangerous Properties of Industrial Materials," John Wiley & Sons, Inc., New York, NY, 2000. This book contains 20,000 entries, each of which gives physical, chemical, and toxicological data about potentially hazardous materials.

R.C.V.

TRACE AND RESIDUE ANALYSIS. Trace analysis is the detection of minute quantities of organic and inorganic materials. As of the mid-1990s, trace analysis is generally recognized as those determinations that represent around 0.0001%, i.e., at the parts per million (ppm) level, where 1 ppm is equivalent to 1 μg/g. Ultratrace analysis, i.e., determination below trace analysis, corresponds to levels below ppm or <μg/g. Residue analysis is the analysis of material left from an operation, i.e., residual.

There are numerous applications for trace or ultratrace analyses in the chemical process industry. Environmental toxicology, in particular, is an area where determination of residues and traces of pesticides and other toxic substances is frequently employed.

Frontiers of Low Level Detection

Extremely low level detection work is being performed in analytical chemistry laboratories. Detection of rhodamine 6G at 50 yoctomole (50×10^{-24} mol) has been reported using a sheath flow cuvette for fluorescence detection following capillary electrophoresis. This represents 30 molecules of rhodamine, a highly fluorescent molecule. See also **Electrophoresis**.

Claims of single molecule detection in liquid samples have been made by combining the high sensitivity of laser-induced fluorescence (lif) and the spatial localization and imaging capabilities of optical microscopy. This technique combines confocal microscopy, diffraction-limited laser excitation, and a high efficiency detector. The probe volume is defined latitudinally by optical diffraction and longitudinally by spherical aberration. Using an unlimited excitation throughout and a low background level, this technique allows fluorescence detection of single rhodamine molecules at a signal-to-noise (S/N) ratio of approximately 10 in 1 ms. The use of confocal fluorescence microscopy can be extended to individual, fluorescently tagged biomolecules, including deoxynucleotides, whether single-stranded primers or double-stranded deoxyribonucleic acid (DNA).

Analysis of single mammalian cells by capillary electrophoresis has been reported using on-column derivatization and laser-induced fluorescence detection. Radioactive tracers are powerful tools for trace detection. A method of labeling proteins using ^{99m}Tc has been described. Radiotracer imaging agents have been used for mapping sympathetic nerves of the heart. The radioiodination of analogues of a calichemicin constituent have been employed as a possible brain-imaging agent.

Samples

Sampling. A sample used for trace or ultratrace analysis should always be representative of the bulk material. The principal considerations are determination of population or the whole from which the sample is to be drawn, procurement of a valid gross sample, and reduction of the gross sample to a suitable sample for analysis (see **Sampling**).

Sample Preparation. Sample contamination must be prevented throughout the sampling procedures. No significant changes should occur in the sample when it is being held for analysis. Sample stabilization generally includes storage at low temperatures; however, any stabilization generally includes storage at low temperatures; however, any stabilization step should be validated. A review of sample composition and properties is advised. This would include number of compounds present, chemical structures (functionality) of compounds, molecular weights of compounds, pK_a values of compounds, uv spectra of compounds, nature of sample matrix (solvent, fillers, etc.), concentration range of compounds in samples of interest, and sample solubility. Significant sample losses can occur during this step because of very small volume losses to glass walls of the recovery containers, pipets, and other glassware.

Solid-phase microextraction (SPME), used as a sample introduction technique for high speed gc, utilizes small-diameter fused-silica fibers coated with polymeric stationary phase for sample extraction and concentration. SPME has been utilized for determination of pollutants in aqueous solution by the adsorption of analyte onto stationary-phase coated fused-silica fibers, followed by thermal desorption in the injection system of a capillary gas chromatograph. Full automation can be achieved using an autosampler.

Polycyclic aromatic hydrocarbons (PAHs) have been extracted from contaminated land samples by *supercritical fluid extraction* (SFE) with both pure and modified carbon dioxide. Removing an analyte from a matrix using SFE requires knowledge about the solubility of the solute, the rate of transfer of the solute from the solid to the solvent phase, and interaction of the solvent phase with the matrix. These factors collectively control the effectiveness of the SFE process, if not of the extraction process in general. The range of samples for which SFE has been applied continues to broaden. Applications have been in the environment, food, and polymers.

Sample preparation techniques that prevent or minimize pollution in analytical laboratories, improve target analyte recoveries, and reduce

sample preparation costs were evaluated with regard to the *microwave-assisted extraction* (MAE) procedure for 187 compounds and four Aroclors listed in EPA Methods 8250, 8081, and 8141A. The results indicate that most of these compounds can be recovered in good yields from the matrices investigated. Comparative studies were performed to evaluate microwave digestion with conventional sample destruction procedures. These included the analysis of shellfish, meats, rocks, and soils. Generally, comparable accuracy at much shorter digestion time was found for the MAE vs the classical digestion method.

Sample Cleanup. The recoveries from a quick cleanup method for waste solvents based on sample filtration through a Florisil and sodium sulfate column are available. This method offers an alternative for analysts who need to confirm the presence or absence of pesticides or PCBs.

Method Validation

Statistically designed studies should be performed to determine accuracy, precision, and selectivity of the methodology used for trace or ultratrace analyses. The reliability requirements for these studies are that the data generated withstand interlaboratory comparisons.

The following principles should be used to establish a valid analytical method: A specific detailed description and protocol should be written (standard operating procedure (SOP)). Each step in the method should be investigated to determine the extent to which environmental, matrix, material, or procedural variables, from time of collection of material until the time of analysis and including the time of analysis, may affect the estimation of analyte in the matrix. A method should be validated for its intended use with an acceptable protocol. Wherever possible, the same matrix should be used for validation purposes. The concentration range over which the analyte will be determined must be defined in the method, on the basis of actual standard samples over the range (standard curve). It is necessary to use a sufficient number of standards to adequately define the relationship between concentration and response. Determination of accuracy and precision should be made by analysis of replicate sets of analyte samples of known concentration from equivalent matrix.

Methodologies

The commonly used methods for ultratrace analyses together with the accepted detection limits are given in Table 1.

Atomic absorption or emission spectrometric methods are commonly used for inorganic elements in a variety of matrices. A radiochemical neutron activation analysis technique for determination of 26 elements, including the emitting elements Th and U and Cu, Fe, K, Na, Ni, and Zn, has been developed. The radiochemical separation was performed by anion exchange on Dowex 1×8 column from HF and $HF{-}NH_4F$ medium, leading to selective removal of the matrix-produced radionuclides ^{46}Sc, ^{47}Sc, ^{48}Sc, and nearly selective isolation of ^{239}Np and ^{233} Pa, the indicator radionuclides of U and Th, respectively. For K, Na, Th, and U, a limit of detection of 30, 0.05, 0.03, and 0.07 ng/g, respectively, was achieved.

The most commonly used approach in thin-layer chromatography (tlc) entails separations on a silica gel plate where the silica gel is coated as a thin layer on a glass plate. The plate is developed using the mobile phase of choice after a sample has been applied to the starting line of the plate. Quantification is achieved directly by scanning the plate or indirectly by scraping and eluting the sample.

TABLE 1. ULTRATRACE ANALYSES METHODS

Method	Minimum amount detected, g
mass spectrometry	
electron impact	10^{-12}
spark source	10^{-13}
ion scattering	10^{-15}
flame emission spectrometry	10^{-12}
liquid chromatography	
ultraviolet detection	10^{-11}
fluorescence detection	10^{-12}
gas chromatography	
flame ionization	10^{-12} to 10^{-14}
electron capture	10^{-13}
combination techniques	
liquid chromatography/mass spectrometry	10^{-12}
gas chromatography/mass spectrometry	10^{-12}
electron capture (negative)/ionization mass spectrometry	10^{-15}

A rapid tlc immunoaffinity chromatographic method has been reported for quantitation in serum of an acute phase reactant, C-reactive protein (CRP), which can differentiate between viral and bacterial infections.

A number of compounds have been quantified by tlc or high performance thin-layer chromatography (hptlc) using absorption or fluorescence scanning densitometry.

Gas chromatography is a technique utilized for separating volatile substances (or those that can be made volatile) between two phases, one of which is a gas. Purge-and-trap methods are frequently used for trace analysis. Various detectors have been employed in trace analysis, the most commonly used being flame ionization and electron capture detectors.

High pressure liquid chromatography (hplc), frequently referred to as simply lc or as high performance liquid chromatography, is used in virtually all fields of chemistry. Nonvolatile or thermally labile compounds are best separated by hplc. Although techniques such as adsorption and ion-exchange chromatography have been used, the technique of choice is reversed-phase liquid chromatography (rplc). In rplc the stationary phase is nonpolar and the mobile phase is polar and its polarity can be suitably changed.

In hplc, detection and quantitation have been limited by availability of detectors. Using a uv detector set at 254 nm, the lower limit of detection is 3.5×10^{-11} g/mL for a compound such as phenanthrene. A fluorescence detector can increase the detectability to 8×10^{-12} g/mL. The same order of detectability can be achieved using amperometric, electron-capture, or photoionization detectors. Hplc is capable of routine determination at the nanogram range.

Increased use of liquid chromatography/mass spectrometry (lc/ms) for structural identification and trace analysis has become apparent. Thermospray lc/ms has been used to identify by-products in phenyl isocyanate precolumn derivatization reactions. Liquid chromatography/thermospray mass spectrometric characterization of chemical adducts of DNA formed during *in vitro* reaction has been proposed as an analytical technique to detect and identify those contaminants in aqueous environmental samples which have a propensity to be genotoxic, i.e., to covalently bond to DNA.

Using capillary hplc, femtomole amounts of recombinant DNA-derived human growth hormone (rhgh) have been successfully detected from solutions at nanomolar concentrations. A sample of rhgh that was recovered from rat serum was analyzed by capillary reversed-phase hplc, using both acidic- and neutral-pH mobile phases, as well as by capillary ion-exchange chromatography. Submicrogram amounts of rhgh were also analyzed by tryptic mapping, using capillary hplc, and the resulting peptides were identified by capillary lc/ms.

Capillary electrophoresis (ce) is an analytical technique that can achieve rapid high resolution separation of water-soluble components present in small sample volumes. The separations are generally based on the principle of electrically driven ions in solution. Selectivity can be varied by the alteration of pH, ionic strength, electrolyte composition, or by incorporation of additives. Typical examples of additives include organic solvents, surfactants, and complexation agents.

Supercritical fluid chromatography (sfc) combines the advantages of gc and hplc in that it allows the use of gc-type detectors when supercritical fluids are used instead of the solvents normally used in hplc. Carbon dioxide, *n*-petane, and ammonia are common supercritical fluids. For example, carbon dioxide employed at 7.38 MPa (72.9 atm) and 31.3°C has a density of 448 g/mL. Derivatization of primary and secondary amines using 9-fluorenylmethyl chloroformate to form a nonpolar, uv-absorbing derivative has been reported.

Immunoassays may be simply defined as analytical techniques that use antibodies or antibody-related reagents for selective determination of sample components. These make up some of the most powerful and widespread techniques used in clinical chemistry. The main advantages of immunoassays are high selectivity, low limits of detection, and adaptability for use in detecting most compounds of clinical interest. Because of their high selectivity, immunoassays can often be used even for complex samples such as urine or blood, with little or no sample preparation.

A two-site immunometric assay of undecapeptide substance P (SP) has been developed. A number of solid-phase automated immunoassay analyzers have been used for performing immunoassays. A number of immunoassay methods have been found useful for environmental analysis (see **Automated Instrumentation**).

Applications

Trace or ultratrace and residue analyses are widely used throughout chemical technology. Areas of environmental investigations, explosives, food, pharmaceuticals, and biotechnology rely particularly on these methodologies.

Environment. Detection of environmental degradation products of nerve agents directly from the surface of plant leaves using static secondary ion mass spectrometry (sims) has been demonstrated.

Some of the methods used for determination of organic pollutants in the environment follow. The most notable are polyaromatic hydrocarbons (PAHs) and volatile organic compounds (VOCs).

Analytes	Methods
n-alkanes	gc/fid
VOCs	prefraction and gc
PAHs	sample clean up and gc
bromoform and other bromine compounds	gc for flame-retardant compounds in air
nitrodibenzopyranone	isomeric separations based on gc
PCDDs and PCDFs	gc/ms
PAH	on-line lc/gc for PAH in air
chlorinated PAH	lc/gc/ms
nitrated PAH	hplc with electrochemical detection
azaarenes	column chromatography, cleanup, and tlc
toluene diisocyanate	micro lc
dimethyl sulfoxide or sulfone	atmospheric pressure chemical ionization (APCI) ms
VOCs	ion trap monitoring
volatile chlorine compounds	fiber-optic emission sensor-based on AA of chlorine
formaldehyde	monitoring tape: hydroxylamine sulfate, methyl yellow
methyl nitrite	nitrogen oxide-indicating tubes with ir detection
VOCs	ir-based methods for on-site analysis
isocyanate species	chemiluminescent techniques
benzene	photoionization detector
hydrazine	coulometric methods
nitrobenzene	piezoelectric sensors
fluorocarbon	metal oxide sensors
perchloroethylene	quartz balance and calorimetric transducer

A variety of organic and inorganic analytes have been analyzed in air and in water.

Explosives. Explosives can be detected using either radiation- or vapor-based detection. The aim of both methods is to respond specifically to the properties of the energetic material that distinguish it from harmless material of similar composition. These techniques are useful for detecting organic as well as inorganic explosives.

Food. Laws and regulations controlling contamination of food were once the province of religious organizations. As far back as the Dark Ages, government set standards. Significant changes have occurred only relatively recently, since the time analytical chemists could characterize most of the substances that comprise food and thus more effectively control contaminants in it. The reliability of data regarding medicated feeds, dairy products. See also **Millerite**, seafood, meat products, fruits and vegetables, and beverages has been reviewed.

The development of analytical strategies for the regulatory control of drug residues in food-producing animals has also been reviewed. Because of the complexity of biological matrices such as eggs, milk, meat, and drug feeds, well-designed off-line or on-line sample treatment procedures are essential. For example, methylmercury in fish was extracted and cleaned using column chromatography and then determined using flameless atomic absorption. A rapid and sensitive electrothermal AA spectrophotometric method using a combination of microwave digestion and palladium as a stabilizer was used for detecting Cd and Pb at sub ppm levels in vegetables and protein in foodstuffs.

Inorganic elements in food can be determined by atomic absorption (AA) methods. These methods have been extensively reviewed.

Pharmaceuticals. Examples of trace and ultratrace analyses of various drugs and pharmaceuticals have been provided throughout. The purity of the active ingredient, its content and availability in dosage form, therapeutic blood levels, delivery to target areas, elimination (urine, feces, and metabolites), and toxicity are always of importance.

A safety profile of a generic drug can differ from that of the brandname product because different impurities may be present in each of the drugs. Impurities can arise out of the manufacturing processes and may be responsible for adverse interactions that can occur.

The subject of impurity analysis of pharmaceutical compounds has been insufficiently addressed in the scientific literature. Many monographs in the *U.S. Pharmacopeia* have nonspecific assay methods. An attempt has been made to address this problem by focusing on specific methodologies and delineating origination and concentration of impurities found in pharmaceutical compounds.

Chiral separations have become of significant importance because the optical isomer of an active component can be considered an impurity. Optical isomers can have potentially different therapeutic or toxicological activities. The pharmaceutical literature is trying to address the issues pertaining to these compounds. Frequently separations can be accomplished by glc, hplc, or ce.

Biotechnology. Particular attention must be paid to the detection of DNA in all finished biotechnology products because of the possibility that such DNA could be incorporated into the human genome and thus become a potential oncogene. The absence of DNA at the picogram-per-dose level should be demonstrated in order to assure the safety of biotechnology products.

The isolation and purification of DNA and ribonucleic acid (RNA) restriction fragments are of great importance in the area of molecular biology. These fragments are the product of site-specific digestion of large pieces of DNA and RNA with enzymes called restriction endonucleases. The fragments may range in size from a few base pairs to tens of thousands of base pairs. An ion-exchange column can provide DNA and RNA separations within one hour, giving resolution equivalent to that obtained with gel electrophoresis. Nucleic acid fragments are then visualized, using on-line uv detection and sample loading from 500 ng to 50 mg.

Molecular biologists are utilizing hplc for characterization and purification of proteins, peptides, and antibodies.

Miscellaneous. Trace analyses have been performed for a variety of other materials.

Thermal neutron activation analysis has been used for archeological samples, such as amber, coins, ceramics, and glass; biological samples; and forensic samples, as well as human tissues, including bile, blood, bone, teeth, and urine; laboratory animals; geological samples, such as meteorites and ores; and a variety of industrial products.

TRACE ELEMENT (Micronutrient). An element essential to plant and animal nutrition in trace concentration, i.e., minute fractions of 1% (1000 ppm or less). Plants require iron, copper, boron, zinc, manganese, potassium, molybdenum, sodium, and chlorine. Animals require iron, copper, manganese, cobalt, selenium, and potassium. Such elements are also called *micronutrients*. Do not confuse with *tracer*.

TRACER. A chemical entity (almost invariably radioactive and usually an isotope) added to the reacting elements or compounds in a chemical process, which can be traced through the process by appropriate detection methods, e.g., Geiger counter. Compounds containing tracers are often said to be "tagged" or "labeled." Carbon-14 is a commonly used

tracer, and radioactive forms of iodine and sodium are also used. Many complex biochemical reactions have been examined in this way (e.g., photosynthesis). Nonradioactive deuterium (hydrogen isotope) is sometimes used, the detection being by molecular weight determination. Radioactive enzymes are also available for tracer studies, e.g., ribonuclease, pepsin, trypsiln, and others.

See also **Radioactivity**.

TRACHYTE. The name of an extrusive, igneous, fine-grained or porphyritic rock, the surface equivalent of syenite. Trachyte is predominant in alkali feldspar and usually contains biotite and augite. Trachyte is an old name, proposed by Brongiart in 1813, and has never been altered or supplanted. It is derived from the Greek, meaning rough.

TRANSACTINIDE ELEMENTS. See **Chemical Elements**.

TRANSACTINIUM EARTHS. A group of chemical elements more frequently termed the Actinides. In order of increasing atomic number, they include actinium, thorium, protactinium, uranium, neptunium, plutonium, americium, curium, berkelium, californium, einsteinium, fermium, mendelevium, nobelium, and lawrencium. See also **Actinide Contraction**.

TRANS-COMPOUND. See **Isomerism**.

TRANSFERENCE NUMBER (Transport Number). Of a given ion in an electrolyte, the transference number is the fraction of total current carried by that ion.

TRANSITION ELEMENT (Transition Metal). Any of a number of elements in which the filling of the outermost shell to eight electrons within a period is interrupted to bring the penultimate shell from 8 to 18 or 32 electrons. Only these elements can use penultimate shell orbitals as well as outermost shell orbitals in bonding. All other elements, called "major group" elements, can use only outermost shell orbitals in bonding. Transition elements include elements 21 through 29 (scandium through copper), 39 through 47 (yttbrium through silver), 57 through 79 (lanthanum through gold) and all known elements from 89 (actinium) on. All are metals. Many are noted for exhibiting a variety of oxidation states and forming numerous complex ions, as well as processing extremely valuable properties in the metallic state.

TRANSITION TEMPERATURE. 1. An arbitrarily defined temperature within the temperature range in which metal fracture characteristics determined usually by notched tests are changing rapidly such as from primarily fibrous (shear) to primarily crystalline (cleavage) fracture.

2. The arbitrarily defined temperature in a range in which, the ductility of a material changes rapidly with temperature.

TRANSMUTATION. The natural or artificial transformation of atoms of one element into atoms of a different element as the result of a nuclear reaction. The reaction may be one in which two nuclei interact, as in the formation of oxygen from nitrogen and helium nuclei (β-particles), or one in which a nucleus reacts with an elementary particle such as a neutron or proton. Thus, a sodium atom and a proton form a magnesium atom. Radioactive decay, e.g., of uranium, can be regarded as a type of transmutation. The first transmutation was performed by the English physicist Rutherford in 1919.

TRANSURANIUM ELEMENTS. The chemical elements with an atomic number higher than 92 (uranium), commencing with 93 (neptunium) and through 110 (darmstadtium) frequently are termed Transuranium elements. Any additional elements that may be identified will be a part of this series. See also **Actinide Contraction** and **Chemical Elements**.

TRAPPED IONS. Charged particles, including electrons and atomic ions, can be stored for long periods of time (days are not uncommon) without the usual perturbations associated with confinement (for example, the frequency shifts associated with the collisions of ions with buffer gases in a more traditional optical pumping experiment). Ions that are stored in electromagnetic "traps" can provide the basis for extremely high-resolution spectroscopy. By using lasers, the kinetic energy of the ions can be cooled to millikelvin temperatures, thus suppressing Doppler frequency shifts. Potential accuracies of frequency standards and clocks based on such experiments are anticipated to be better than one part in 10^{15}. The current time standard (cesium clock) has an accuracy of one part in 10^{13} or less. See also **Mass Spectrometry**.

Storage has mainly been achieved in four types of traps: (1) the radio frequency or Paul trap; (2) the Penning trap; (3) the Kingdon electrostatic trap; and (4) the magnetostatic (magnetic bottle) trap. The principles, advantages, and disadvantages of these traps are detailed by D.J. Wineland (*Science*, **226**, 395–400, Oct. 26, 1984).

TRAVERTINE. Carbonated waters dissolve large amounts of calcium carbonate, especially under high temperature. Such waters reaching the earth's surface as hot springs often deposit the calcium carbonate, in great quantities. This material is called travertine from the ancient name for Tivoli, Italy, where a very thick deposit occurs. Travertine may be compact, crystalline, fibrous or, if rapidly deposited, spongy and porous. The less compact varieties are known as tufa. Travertine is being formed at the Mammoth Hot Springs, Yellowstone National Park and at many other localities. A banded travertine used as an ornamental stone is called onyx marble or Mexican onyx.

TREMOLITE. [CAS: 1332-21-4]. The mineral tremolite is a calcium-magnesium silicate corresponding to the formula $Ca_2Mg_5Si_8O_{22}(OH)_2$, belonging to the amphibole group. The replacement of magnesium by ferrous iron causes tremolite to approach actinolite in composition. Tremolite is monoclinic, developing bladed prismatic crystals, but it is frequently found in compact columnar, granular, or fibrous masses. The perfect prismatic cleavage at angles of 56° and 124° typical of this group is to be noted; hardness, 5–6; specific gravity, 2.9–3.1; luster, vitreous to silky; color, varies from white or whitish-gray through shades of green or greenish-yellow; transparent to opaque. Tremolite is formed as a result of contact metamorphism and occurs in marbles, dolomites, and schists. It may alter to talc. Tremolite is found in Switzerland, in the St. Gotthard region, being named for the Tremola Valley, and is common elsewhere in Europe. In the United States it occurs in Maine, Pennsylvania, and New York. In Canada tremolite has been found in Quebec and Ontario.

Hexagonite is a pinkish-purple variety of tremolite which contains a small amount of manganese. So called because it was at first believed to be hexagonal. It has been since shown to be monoclinic, and is found in St. Lawrence County, New York. Some nephrite and asbestos is tremolite.

See also terms listed under **Mineralogy**.

TRIACETATE. See **Cellulose Ester Plastics (Organic)**; **Fibers**.

TRICARBOXYLIC ACID CYCLE. See **Carbohydrates**.

TRIDYMITE. The mineral tridymite is, like quartz, silicon dioxide, SiO_2, but is a high-temperature variety, probably stable above 870°. It has a conchoidal fracture; is brittle; hardness, 7; specific gravity, 2.28–2.33; vitreous luster; usually colorless and transparent. It is found chiefly in volcanic rocks of the more acidic types like rhyolite, tachyte, and andesite. It is not a particularly uncommon mineral, occurring in Germany, France, Italy, Japan, the Island of Martinique, Mexico, and in the United States in Wyoming and Washington. Tridymite is hexagonal but when heated to about 1,470°C passes into an isometric form, cristobalite, which was first noted in the andesitic lavas of the Cerro San Cristobal, Pachuca, Mexico, together with tridymite. Cristobalite has been found also in California and in Germany.

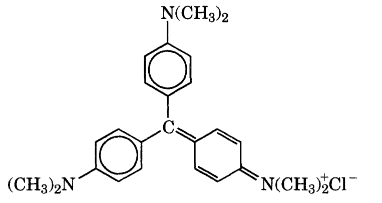
TRIPHENYLMETHANE AND RELATED DYES. Triphenylmethane dyes are of brilliant hue, exhibit high tinctorial strength, are relatively inexpensive, and may be applied to a wide range of substrates. They are seriously deficient in fastness properties, especially fastness to light and washing. Consequently, the use of triphenylmethane dyes on textiles such as wool, silk, and cotton has decreased as dyes from other classes with superior lightfastness and washfastness properties have become available. Interest in this class of dyes was revived with the introduction of polyacrylonitrile fibers. See also **Acrylonitrile Polymers**; and **Fibers**. Triphenylmethane dyes are readily adsorbed on this fiber and show surprisingly high lightfastness and washfastness properties, compared with the same dyes on natural fibers. However, the durability of acrylic fibers created an even greater demand for fastness properties.

The triarylmethane dyes are broadly classified into the triphenylmethanes (CI 42000–43875), diphenylnaphthylmethanes (CI 44000–44100), and miscellaneous triphenylmethane derivatives (CI 44500–44535). The triphenylmethanes are classified further on the basis of substitution in the aromatic nuclei, as follows: (*1*) diamino derivatives of triphenylmethane, i.e., dyes of the malachite green series (CI 42000–42175); (*2*) triamino derivatives of triphenylmethane, i.e., dyes of the fuchsine, rosaniline, or magenta series (CI 42500–42800); (*3*) aminohydroxy derivatives of triphenylmethane (CI 43500–43570); and (*4*) hydroxy derivatives of triphenylmethane, i.e., dyes of the rosolic acid series (CI 43800–43875). Monoaminotriphenylmethanes are known but they are not included in the classification because they have little value as dyes.

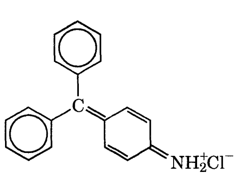
Chemically, the triarylmethane dyes are monomethine dyes with three terminal aryl systems of which one or more are substituted with primary, secondary, or tertiary amino groups or hydroxyl groups in the para position to the methine carbon atom. Additional substituents such as carboxyl, sulfonic acid, halogen, alkyl, and alkoxy groups may be present on the aromatic rings. The number, nature, and position of these substituents determine both the hue or color of the dye and the application class to which the dye belongs.

Structure

The triarylmethane dyes are generally considered to be resonance hybrids. However, for convenience, usually only one hybrid is indicated, as shown for crystal violet, CI Basic Violet 3 (**1**), for which $\lambda_{max} = 589$ nm.



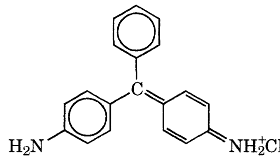
(**1**)



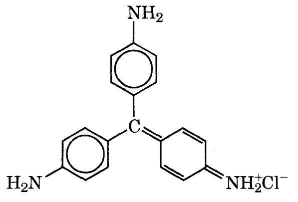
(**2**)

The ortho hydrogen atoms surrounding the central carbon atom show considerable steric overlap. Therefore, it can be assumed that the three aryl groups in the dye are not coplanar, but are twisted in such a fashion that the shape of the dye resembles that of a three-bladed propeller. Substitution in the para position of the three aryl groups determines the hue of the dye. When only one amino group is present, as in fuchsonimine hydrochloride, $\lambda_{max} = 440$ nm (**2**), the shade is a weak orange-yellow.

When at least two or more amino groups are present in different rings, the resonance possibility is greatly increased, resulting in a much greater intensity of absorption and in a strong bathochromic shift to longer wavelengths, e.g., Doebner's violet (**3**), $\lambda_{max} = 562$ nm, which is a reddish violet, and pararosaniline (**4**) $\lambda_{max} = 538$ nm, which is a bluish violet. The amino derivatives of commercial value contain two or three amino groups.



(**3**)



(**4**)

A further strong bathochromic shift is observed as the basicity of the primary amines is increased by *N*-alkylation, e.g., malachite green, CI Basic Green 4, $\lambda_{max} = 621$ nm.

Chemical Properties

Although many triarylmethane dyes are prepared by the oxidation of leuco bases, they are usually destroyed by strong oxidizing agents. The triarylmethane dyes are extremely sensitive to photochemical oxidation, a fact which accounts for their poor lightfastness on natural fibers. There are many factors which affect the rate of fading (degradation) of the triarylmethane dyes on natural and synthetic fibers. Several studies have revealed that *N*-dealkylation occurs simultaneously with the cleavage and contributes to the photodegradation. *N*-Dealkylation is a general phenomenon in dye photochemistry.

Triarylmethane dyes are reduced readily to leuco bases with a variety of reagents. Reduction with titanium trichloride (Knecht method) is used for rapidly assaying triarylmethane dyes.

The direct sulfonation of alkylaminotriphenylmethane dyes gives mixtures of substituted products. Although dyes containing anilino or benzylamino groups give more selective substitution, a sulfonated intermediate such as 3[(*N*-ethyl-*N*-phenyl-amino)methyl]benzenesulfonic acid (ethylbenzylanilinesulfonic acid) is the preferred starting material.

Dyes containing highly alkylated amino groups are prepared from highly alkylated intermediates and not by direct alkylation of dyes carrying primary amino groups. 4, 4′, 4″-Triaminotriphenylmethane (pararosaniline) may, however, be *N*-phenylated with excess aniline and benzoic acid to give the greenish blue, *N*, *N*′, *N*″-triphenylaminotriphenylmethane hydrochloride, CI Solvent Blue 23, $\lambda_{max} = 586$ nm.

Triarylmethane dyes can be converted into two types of insoluble compounds, which are used industrially as pigments. Both are salts of triarylmethane dyes. Known as pigment lakes, these complexes provide clean, brilliant red and violet shades. These pigments are used in printing inks, especially packaging and special printing inks. The second type of pigments derived from triarylmethane dyes are known as alkali blues. The main use of the alkali blues is as shading pigments in inks based on carbon black, where an inexpensive blue component is needed to correct the natural brown tone of the base pigment. The main area of application is in printing inks, particularly offset, letterpress, and to a lesser extent in aqueous flexographic inks. They are used to color ribbons for typewriters and also to blue copy paper.

Manufacture

The preparation of tri arylmethane dyes proceeds through several stages; formation of the colorless leuco base in acid media, conversion to the colorless carbinol base by using an oxidizing agent, e.g., lead dioxide, manganese dioxide, or alkali dichromates, and formation of the dye by treatment with acid. The oxidation of the leuco base can also be accomplished with atmospheric oxygen in the presence of catalysts.

Aldehyde Method. This method is generally used for the preparation of diaminotriphenylmethane dyes or hydroxytriphenylmethane dyes. The central carbon atom is derived from an aromatic aldehyde or a substance capable of generating an aldehyde during the course of the condensation. For example, Malachite green is prepared by heating benzaldehyde under reflux with a slight excess of dimethylaniline in aqueous acid.

Ketone Method. In the ketone method, the central carbon atom is derived from phosgene. A diarylketone is prepared from phosgene and a tertiary arylamine and then condenses with another mole of a tertiary arylamine (same or different) in the presence of phosphorus oxychloride or zinc chloride. The dye is produced directly without an oxidation step. Thus, ethyl violet, CI Basic Violet 4, is prepared from 4, 4′-bis(diethylamino)benzophenone with diethylaniline in the presence of phosphorus oxychloride. This reaction is very useful for the preparation of unsymmetrical dyes.

Diphenylmethane Base Method. In this method, the central carbon atom is derived from formaldehyde, which condenses with two moles of an arylamine to give a substituted diphenylmethane derivative. The methane base is oxidized with lead dioxide or manganese dioxide to the benzhydrol derivative. The reactive hydrols condense fairly easily with arylamines, sulfonated arylamines, and sulfonated naphthalenes. The resulting leuco base is oxidized in the presence of acid.

Benzotrichloride Method. The central carbon atom of the dye is supplied by the trichloromethyl group from *p*-chlorobenzotrichloride. Both symmetrical and unsymmetrical triphenylmethane dyes suitable for acrylic fibers are prepared by this method.

Health, Safety, and Environmental Information

In the 1960s, problems were encountered with the interpretation of toxicological studies on animals given triarylmethane dyes used as food colorants. Conflicting test data have been obtained on various triarylmethane dyes. Positive and negative results for the same dye in different assays have only led to more genotoxic studies. In the U. S. CI Food Violet 2 was delisted for use in food, drugs, and cosmetics in 1973. There are triarylmethane dyes which have also been delisted worldwide for use in food, e.g., Guinea Green B, CI Food Green 1 (CI 42085), and Violet BNP, CI Food Violet 3.

The triarylmethane dyes of the rosaniline family, e.g., fuchsine and crystal violet, show similar toxic responses in assays. They are moderately

toxic after acute exposure, but the effects usually pass within a couple of days. These effects are no cause for alarm as long as the dyes are not permitted for food use or contact. There is evidence that the toxicological effects might be the result of impurities, e.g., aromatic amines, or of certain functional groups, notably amino substituents found in the dyes.

The toxicity of dyes to aquatic organisms has also been investigated, with most of the work done on fish. In these studies, over 3000 dyes in common use were tested, of which 27 dyes had a LC_{50} around 0.05 mg/L. Ten of these cases had triarylmethane structures.

Environmental Concerns

The main route by which dyes enter the environment is via wastewater, both from their manufacture and their use. Accurate data on dyes released into the environment are not available, although lists of materials released to the environment from the processes operated for the production of some triarylmethane dyes have been reported.

Uses

Present usage of triarylmethane dyes is confined mainly to nontextile applications. Substantial quantities are used in the preparation of organic pigments for printing inks, pastes, and for the paper printing trade, where cost and brilliance of shade are more important than lightfastness. Triarylmethane dyes and their colorless precursors, e.g., carbinols and lactones, are used extensively in heat-, light-, and pressure-sensitive recording materials for high speed photoduplicating and photoimaging systems and for the production of printing plates and integrated circuits. They are also used for specialty applications such as tinting automobile antifreeze solutions and toilet sanitary preparations, in the manufacture of carbon paper, in ink for typewriter ribbons, and ink jet printing for high speed computer printers.

In addition to the dyeing and printing of natural and acrylic fibers, triarylmethane dyes are suitable for the coloration of other substrates such as paper, ceramics, leather, fur, anodized aluminium, waxes, polishes, soaps, plastics, drugs, and cosmetics. Several triarylmethane dyes are used as food colorants and are manufactured under stringent processing controls.

Triarylmethane dyes can be used for the coloration of glass. Other high technology applications using triarylmethane dyes include electrophotography and optical data storage.

Related Dyes

Diphenylmethane Dyes. The diphenylmethane dyes are usually classed with the triarylmethane dyes. The dyes of this subclass are ketoimine derivatives, and only three such dyes are registered in the *Colour Index*. They are Auramine O CI Basic Yellow 2 (CI 41000), Auramine G, Basic Yellow 3 (CI 41005), and CI Basic Yellow 37 (CI 41001). These dyes are still used extensively for the coloration of paper and in the preparation of pigment lakes.

Phthaleins. Dyes of this class are usually considered to be triarylmethane derivatives. Phenolphthalein and phenol red are used extensively as indicators in colorimetric and titrimetric determinations. See also **Hydrogen-Ion Activity**.

Heteroarylmethane Dyes. Dyes of this class usually have either one or two heteroaryl groups attached to the methane carbon atom. Trihetarylmethane dyes are known and have been investigated for their pharmacological activity as well as their color characteristics. These types of triarylmethane dyes and their derivatives are used as color formers in thermoreactive and pressure-sensitive recording materials.

Triarylmethane Dyes with Near-Infrared Absorption. The long wavelength absorption bands of triarylmethane dyes can be shifted into the near-infrared region, but the dyes still remain colored because other absorption bands are shifted to or stay in the visible region. These types of triarylmethane dyes and their derivatives have been claimed as infrared absorbers for optical information recording media and security devices, and as organic photoconductors for use in lithographic plate production.

TRIPHYLITE. This mineral is a phosphate of lithium and ferrous iron, $LiFePO_4$. It crystallizes in the orthorhombic system but usually is characterized by large cleavable masses. The hardness is 4.5–5.0; specific gravity, 3.42–3.56, vitreous to resinous luster, translucent, and bluegray color. The mineral occurs as a rare primary mineral in granitic pegmatites and, when available in large quantities, is a source of lithium. Worldwide occurrences include Bavaria, Finland, Sweden, and in the United States, New Hampshire, Maine, and South Dakota.

TRIPLE BOND. A highly unsaturated linkage between the two carbon atoms of acetylenic compounds (alkynes), typified by acetylene ($HC \equiv CH$).

See also **Bond (Chemical)**; and **Chemical Elements**.

TRIPLE BOND (Carbon). See **Organic Chemistry**.

TRIPLE POINT. The temperature and pressure at which the solid, liquid, and vapor of a substance are in equilibrium with one another. Also applied to similar equilibrium between any three phases, i.e., two solids and a liquid, etc. The triple point of water is +0.072 C at 4.6 mm Hg; it is of special importance because it is the fixed point for the absolute scale of temperature.

See also **Three-Phase Equilibrium**.

TRIPOLITE. A term frequently used synonymously with diatomaceous earth, but more particularly with reference to diatomaceous earth from Tripoli in North Africa. See also **Diatom**; and **Diatomite**.

TRITIUM. The radioactive isotope of hydrogen, with a mass number 3, is termed tritium. It is one form of heavy hydrogen, the other form being deuterium. See also **Nuclear Power Technology**.

TRIVIAL NAME. The name applied by early chemists to a number of simple organic compounds, usually based on their sources or properties, e.g., acetone and acetic acid, from Latin *acetum* (vinegar), urea from urine, glucose and glycerol from Greek *glyc*-(sweet). Such names remained in common use regardless of the systematic nomenclature later developed.

TUNGSTEN. [CAS: 7440-33-7]. Chemical element, symbol W, at. no. 74, at. wt. 183.85, periodic table group 6, mp 3390–3420°C, bp 5,660°C, density 19.3 g/cm^3. Two forms of metallic tungsten are known: α-tungsten, which has a body-centered cubic crystal structure, and β-tungsten, which has a face-centered cubic crystal structure. The metal exhibits the phenomenon of passivity so that it is quite resistant to chemical action even though it has a strong reducing action when a fresh surface is exposed, or in potentiometric titrations. Tungsten is a silver-white to steel-gray, brittle, hard metal; not oxidized by air at ordinary temperature, but burns at high temperature, best dissolved by a mixture of hydrofluoric and HNO_3 acids. Tungsten has four naturally occurring isotopes ^{180}W, and ^{182}W through ^{184}W. ^{180}W is radioactive with a half-life of approximately 3×10^{14} years. Six other radioactive isotopes have been identified ^{176}W through ^{178}W, ^{181}W, ^{185}W, ^{187}W, and ^{188}W. All have half-lives considerably less than 4 months in length. Tungsten does not occur in the free state and is a relatively scarce element, making up an estimated 7×10^{-3}% of the Earth's crust. The tungsten content of seawater is estimated at about 950 pounds per cubic mile. Although the tungsten mineral *wolframite* (iron manganese tungstate) was described as early as 1574, it was then mistaken as a mineral of tin. The term *tungsten* first appeared about 1758. K.W. Scheele identified tungstic oxide in 1781, after which the calcium tungstate mineral *scheelite* was named. The first metallic tungsten was produced by J.J. d'Elhuyar and F. d'Elhuyar in 1783 by the carbon reduction of the oxide. W.D. Coolidge obtained a patent in 1908 for making ductile tungsten wire for use in incandescent lamps. Divers authorities accredit Scheele or the d'Elhuyar brothers with the discovery of the element. With exception of the United States, the element generally is referred to as *wolfram.* First ionization potential of tungsten is 7.98 eV. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^4 6s^2$. Ionic radius

W^{+4}0.68 Å, W^{+6}0.65 Å. Metallic radius 1.3704$_5$ Å. Other important physical properties of tungsten are given under **Chemical Elements**.

Usually tungsten minerals are found in pegmatites, sills, and batholiths. Minerals often accompanying tungsten minerals are cassiterite, quartz, feldspar, sulfides, arsenites, apatite, calcite, molybdenite, and bismuthinite. Several of these minerals are described under separate alphabetical entries. In order of decreasing magnitude, tungsten deposits occur in the People's Republic of China, the United States, Korea, Bolivia, Portugal, Burma, and Australia. Deposits also are found in at least ten other areas. In the United States, the most significant deposits are found in California, Nevada, South Carolina, Idaho, and Colorado. Tungsten concentration in the ores found in the United States run from 0.5% to 3% WO_3 (20 pounds 9 kilograms of WO_3 contains about 15.9 pounds 7.2 kilograms of W). High-purity tungsten metal is prepared by extracting the tungsten from the ore by use of a strong alkali hydroxide solution at the boiling point. The alkali-metal carbonate or hydroxide thus obtained then is fused to form the water-soluble, alkali-metal tungstate. Where NH_4OH is used, the product is ammonium tungstate (NaOH yields sodium tungstate). The compound is reduced to metal powder. Conversion of the powder to massive metal is done by pressing, sintering, and mechanical working at high temperatures. In another process, the ore is fused with sodium carbonate and nitrate to yield sodium tungstate. Reduction of the oxide is accomplished by heating with carbon or hydrogen, whereupon tungsten metal is yielded.

Uses

Approximately one-half of the tungsten produced is in the form of sintered tungsten carbides. These compounds are used for cutting tools and wear-resistant parts. About 15% of production is consumed for making wire used in lamps and also for various shapes used in aerospace and defense products. Another 15% of production is used for high-temperature alloys and powder metallurgy. Approximately 10% goes into high-speed tools. The remaining production goes into a wide variety of applications.

Tungsten carbide, WC, is extremely hard (9.5 on the Mohs scale; diamond = 10) and has a melting point of 2,870°C. This combination of hardness and high-temperature stability makes it an excellent material for cutting tools. Additionally, the wear-resistant properties are excellent, accounting for the use of tungsten carbide for dies for hot and cold working of wire, rod and tubing, mining tools, snow-tire studs, and ball-point pens. For hard carbide tools and dies, tungsten carbide in the form of fine powder (1–10 micrometer particle size) is bonded with cobalt.

Special carbide tools also will often contain various percentages of titanium, tantalum, niobium (columbium), and hafnium carbides, along with the tungsten carbide. Chromium and vanadium carbides are also added to produce special, fine-grain-size grades of cemented tungsten carbide-cobalt materials. See Fig. 1.

For hard-facing applications, fused tungsten carbide is used. Tungsten also forms the ditungsten carbide W_2C, which has a melting point of 2,860°C. However, the term *tungsten carbide* usually refers to the mono compound. WC generally is made by combining tungsten metal powder with finely divided lampblack. The mixture then is heated to about 1,500°C. A variety of tungsten powders are made which then are subjected to various powder metallurgy techniques to form numerous shapes with a wide range of characteristics. Tungsten carbide can also be manufactured by a so-called menstrum process, which employs calcium carbide and aluminum metal to reduce scheelite via a thermite reaction, with the tungsten carbide recovered by acid washing.

Tungsten wire, including pure (unalloyed), doped nonsag; (potassium silicate and aluminum chloride or nitrate doped), and thoriated and zirconiated types are used extensively in applications such as filaments for incandescent lamps, thermocouples, arc-lamp electrodes, electrochemical electrodes, and instrument springs. See Fig. 2. Tungsten disks are used for electrical contacts; tungsten is used in glass-to-metal seals, where the coefficient of thermal expansion of tungsten is close to that of hard borosilicate glass; and tungsten pads are used in connection with silicon semiconductors because of the high thermal conductivity of tungsten and good match of the coefficient of thermal expansion of tungsten with that of silicon.

Compositions of silver and tungsten and of copper and tungsten find application as electrical contacts where they are subject to severe arcing. As a shield or as containers for radioactive materials, heavy-metal alloys of tungsten alloyed with about 7% nickel and 4% copper are effective. The same alloys also find other uses where high density is required, as in gyroscope rotors, counterweights in aircraft, and self-winding watch parts. Alloys of cobalt, chromium, and tungsten also find use in cutting tools, dies, and wear-resistant parts. The function of tungsten in steel is that of forming stable carbides, strengthening ferrite, and refining the grain size for retaining high hardness at elevated temperatures—a requirement of highspeed steels.

Tungsten chemicals find limited use in inks, paints, enamels, dyes, and glass manufacture. Some tungsten compounds and their derivative phosphors find use in x-ray screens, television picture tubes, and luminescent light sources.

Chemistry and Compounds

In keeping with its $5d^4 6s^2$ electron configuration, tungsten forms many compounds in which its oxidation state is 6+, just as molybdenum does. It forms divalent and tetravalent compounds to about the same extent as molybdenum but its trivalent and pentavalent compounds are somewhat fewer. Its anion chemistry is closely akin to that of molybdenum.

Among the divalent compounds of tungsten, the diiodide, WI_2, dibromide, WBr_2, and the dichloride, WCl_2, are among the most clearly characterized; they all hydrolyze, although the iodide reacts only with warm water. Like molybdenum, tungsten(II) has a complex chloroion, $[W_6Cl_8]^{4+}$ which, however, is much more easily oxidized than its molybdenum analog.

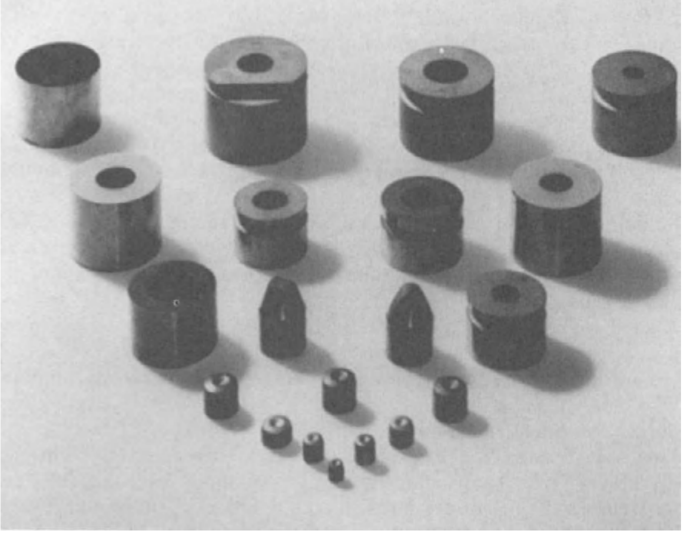

Fig. 1. Cemented tungsten carbide compacts and mud nozzles for oil well drilling. (*Fansteel*)

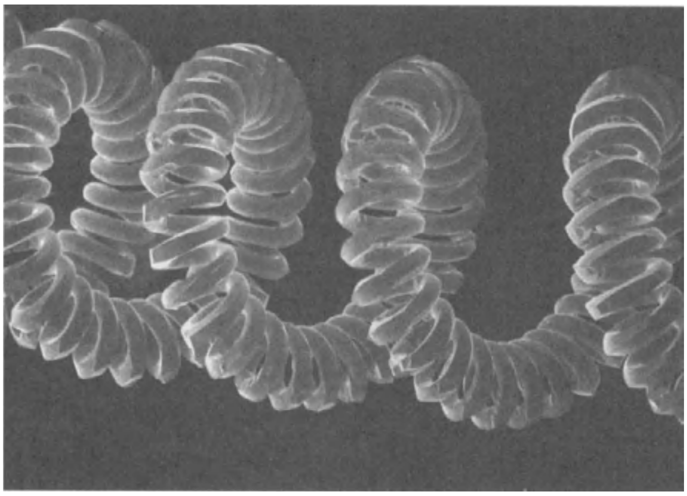

Fig. 2. Scanning electron photomicrograph of a nonsagging tungsten filament taken after several hundred hours of operation at 2500°C in a 60-watt light bulb. (*After Wittenaur, Nieh, and Wadsworth*)

Trivalent tungsten occurs rarely in simple compounds, other than certain high-temperature products such as one of the borides, WB, one of the phosphides, WP, and the complexes. Among the latter is the ion $[W_2Cl_9]^{3-}$ in which the two tungsten atoms participate in a ClWClWCl bridging structure, as they do in a W_2Cl_6 structure.

In addition to the tungsten(II) boride mentioned above, the element forms at least two other borides, W_2B and WB_2; it forms a similar series of phosphides, W_2P, WP, and WP_2 as well as WO_2 (brown oxide), W_4O_{11} (blue oxide), and WO_3 (yellow oxide), and two sulfides, WS_2 and WS_3. The tungsten(IV) oxide and sulfide are representative of the simple tetravalent compounds, which also include a tetrabromide, WBr_4, and tetraiodide, WI_4. Like the dihalides, these tetrahalides undergo hydrolysis quite readily.

Among the best known simple pentavalent tungsten compounds are the pentachloride, WCl_5, and the pentabromide, WBr_5. As is true of tungsten(IV), tungsten(V) forms complexes.

By far the greatest number of tungsten compounds are those in which the element is hexavalent. These include all common halides except the iodide, i.e., WF_6, WCl_6, as well as a number of oxyhalides, WOF_4, $WOCl_4$, WO_2Cl_2, $WOBr_4$, and WO_2Br_2, the trioxide, trisulfide, diboride, and diphosphide already mentioned, various complexes and organometallic compounds, and the anions.

Tungsten trioxide dissolves in hot alkali metal hydroxide solutions to yield in more or less hydrated form, the tungstate ion, WO_4^{2-}. However, the ionic species that exist in solution are more complex than mere hydration of the WO_4^{2-} would indicate, and this is especially true of the compounds obtained from such solutions. There are, however, two simple forms of the orthotungstic acid: H_2WO_4, which is precipitated upon addition of HCl to a hot tungstate solution, and $H_2WO_4 \cdot H_2O$, which is similarly obtained from a cold solution. Neutralization of a tungstate solution under most conditions yields, upon crystallization, much more complex salts. The acidic groups condense, with elimination of water, to form complexes, that can be crystallized as salts, which can be regarded as derived from "poly" acids. When such salts have only one kind of metal atom (e.g., W) in their anions, they are called *isopoly acids*; when they have more than one kind, they are called *heteropoly acids*. The latter group comprises an entire field of tungsten chemistry (as well as that of molybdenum and other elements.); the tungstophosphates are important in analysis and other applications. Other examples are the heteropoly acid salts formed by tungsten with oxyanions of boron, silicon, germanium, tin, arsenic, titanium, zirconium, and hafnium. In particular, the 6-series and the 12-series, containing, respectively, 6 and 12 tungsten atoms per molecule, have been extensively investigated.

Other interesting compounds are the "tungsten blues," complex oxides of colloidal nature, obtained by reduction of tungstates in alkaline solution. At higher temperatures, reduction of tungstates (of main group 1 and 2 elements) by alkali metal, hydrogen, zinc, tungsten, or electrolysis yields the semimetallic "tungsten bronzes," formulated as M_nWO_3, where M is the alkali metal and n is less than 1. They have cubical structures with W−O−W groups forming the sides, and the alkali or alkaline earth atom randomly located in the center of some of the cubes. The resulting extra electrons are considered to distribute over the entire structure, giving it metallic properties.

Tungsten forms many other complexes. Of particular interest are the octacyano complexes, containing eight cyanide, CN^- ions coordinated to a single tetravalent or pentavalent tungsten ion, $W(CN)_8^{4-}$ or $W(CN)_8^{3-}$, the latter being exceptionally stable, and forming octacyanotungstic(V) acid, $H_3[W(CN)_8] \cdot 6H_2O$, which is known in salts. Similar complexes are known for molybdenum, rhenium and osmium. The fluorocomplex of tungsten(VI) has the structure $[WF_8]^{2-}$ and forms salts with the higher alkali metals, potassium, rubidium and cesium.

Like molybdenum and chromium, tungsten forms a number of cyclo pentadienyl compounds which are also carbonyls, e.g., $C_5H_5W(CO)_3H$, $C_5H_5W(CO)_3CH_3$, $C_5H_5W(CO)_3C_5H_5$, $C_5H_5(CO)WW(CO)C_5H_5$, and $C_5H_5(CO)_3WW(CO)_3C_5H_5$. Tungsten(VI) also forms several other orga nometallic compounds, e.g., $W(OC_6H_5)_6$ and $W(OC_6H_4CH_3)_6$, as well as a simple carbonyl, $W(CO)_6$.

An excellent and comprehensive review of tungsten and its alloys is given in the Wittenauer reference listed.

TURBIDIMETRY. The cloudiness in a liquid caused by the presence of finely divided, suspended material is termed *turbidity*. A turbidimeter measures this quality by determining the reduction in transmission of light that is caused by interposing a turbid solution between a light source and a detector, such as the eye or photocell. By using a known volume of solution in comparison with a standard, the instrument makes it possible to determine the mass effect, attributable to the number and size of the particles in the solution, and thus the quantitative amount of material present. Turbidimetric methods are similar to colorimetric procedures in that both involve measurement of the intensity of light transmitted through a medium. They differ in that the light intensity is attenuated by scattering in turbidimetry and by absorption in colorimetry. Both determinations may use similar instrumentation. Several designs of combined nephelometers, turbidimeters, and colorimeters are available.

Turbidimetry is applicable to the determination of suspended material in liquids encountered in nature and in manufacturing processes. Numerous uses are found in water treatment plants, sewage works, power and stream generating plants, beverage bottling plants, and petroleum refineries. The turbidity may be due to a single chemical substance, or it may be due to a combination of several components. For example, silica may be determined in the approximate concentrations of 0.1 to 150 parts per million, expressed as SiO_2. Sometimes, composite turbidities are expressed as equivalent to silica. Higher concentrations may be determined by dilution. Numerous applications are possible in which a turbidity is developed from the test sample under controlled conditions. A widely used determination is that of sulfate, after the addition of barium chloride to an unknown sample to form a suspension of barium sulfate. The procedure is particularly applicable within the concentration range of 0.2 to 100 parts per million sulfate. Routine procedures have been developed for the determination of sulfur in coal, oil, and other organic materials in which the sample first is fused in a sodium peroxide bomb prior to precipitation of the sulfur as barium sulfate.

The *Parr turbidimeter* is an extinction type instrument, which consists of a cylinder to contain the turbid suspension, a lamp filament of fixed intensity at the base, and an adjustable plunger through which visual observation is made. Measurement is made of the depth of turbid medium necessary to extinguish the image of the lamp filament. Standard suspensions are used to prepare a calibration curve, which is a plot of depth *vs.* concentration.

The *Hellige turbidimeter* is also a variable depth type of instrument using visual detection. A combination of vertical and horizontal illumination of the sample and a split ocular permit the eye to function merely to compare the intensities of two images simultaneously appearing in the ocular. This is a special form of double-beam operation, and the intensity emitted by the light source need not be extremely constant from one sample to another. Adjustment is made of a slit in the path of the direct, or vertical, illumination of the sample, and the calibration curve consists of a plot of this slit opening *vs.* concentration.

TURBULENT FLOW. A condition of fluid flow in a closed conduit that is above a critical velocity. In this condition, there is a random, irregular

motion of the fluid particles in directions transverse to the axis of the main flow. This is converse to the condition of laminar or streamline flow. See also **Laminar Flow**.

At velocities greater than the critical, the fluid velocity profile in the conduit is uniform across the conduit diameter except for a thin layer of fluid at the conduit wall. This *boundary layer* continues to move in laminar flow. In connection with flow measurement, most flowmeters have constant coefficients under turbulent flow conditions. Some flowmeters have the advantage of constant coefficients over Reynolds Number ranges encompassing both turbulent and laminar flows. See also **Fluid and Fluid Flow**; and **Reynolds Number**.

TURPENTINE. See **Resins (Natural)**.

TURQUOISE. The mineral turquoise is a hydrated phosphate of aluminum and copper. Its exact composition is doubtful, the formula may be expressed $CuAl_6(PO_4)_4(OH)_8 5 \cdot H_2O$; iron is often present. This mineral is found in minute triclinic crystals, but chiefly massive as seams and crusts. The fracture is conchoidal; hardness, 5–6; specific gravity, 2.6–2.8; luster, soft waxy; color, may be various shades of blue, bluish-green and green; essentially opaque. It takes a good polish and the sky-blue varieties have long been used as a gem material. Unfortunately, many beautiful blue stones in time change their color to some greenish hue, usually not attractive, rendering them practically valueless.

For hundreds of years turquoise has been mined in Iran, where it is found with limonite filling crevices in a brecciated trachyteporphyry, and because it found its way into Europe through Turkey, it became known as turquoise, from the French word *turque*, Turkish. Other mines were worked by the Egyptians in ancient times on the Sinai Peninsula. Turquoise is also found in Siberia, Turkestan, Saxony and France; and in the United States in Arizona, California and New Mexico. A blue stone that has passed for turquoise is in reality odontolite, from the Greek meaning tooth, usually fossil teeth or bones colored with iron phosphate. Odontolite is softer than true turquoise, has a somewhat higher specific gravity, 3.0–3.5, and may be distinguished by chemical tests, or by a microscopical examination which will reveal its organic structure.

TWINNING (Crystal). A process in which a region in a crystal assumes an orientation which is symmetrically related to the basic orientation of the crystal. Usually, layers of atoms within this region are translated with respect to a basic plane (the twinning plane). Each atomic plane is displaced by a distance which is proportional to its distance from the twinning plane. Bands of metal (twin bands) thus assume a lattice structure which is the mirror image of the unchanged portion of the lattice. See also **Mineralogy**.

TWITCHELL PROCESS. One of the very early methods for the hydrolysis of fats and oils on an industrial scale. The key to the process is *Twitchell's reagent*, which is prepared by interacting oleic acid, benzene, and H_2SO_4. The product sometimes is termed *sulfobenzenestearic acid*. The agent accelerates hydrolysis. Naphthalene may be used in place of benzene in the reagent with the assigned $C_{18}H_{35}O_2 \cdot C_{10}H_6SO_3H$.

TYNDALL EFFECT. A phenomenon first noticed by Faraday (1857). When a powerful beam of light is sent through a colloidal solution of high dispersity, the sol appears fluorescent and the light is polarized, the amount of polarization depending upon the size of the particles of the colloid. The polarization is complete, if the particles are much smaller than the wavelength of the radiation. See also **Nephelometry**.

TYNDALL, JOHN (1820–1893). John Tyndall was a man of science: draftsman, surveyor, physics professor, mathematician, geologist, atmospheric scientist, public lecturer, and mountaineer. Throughout the course of his Irish and later, English life, he was able to express his thoughts in a manner none had seen or heard before. His ability to paint mental pictures for his audience enabled him to disseminate a popular knowledge of physical science that had not previously existed. Tyndall's original research on the radiative properties of gases as well as his work with other top scientists of his era opened up new fields of science and laid the groundwork for future scientific enterprises.

In January 1859, Tyndall began studying the radiative properties of various gases. Part of his experimentation included the construction of the first ratio spectrophotometer, which he used to measure the absorptive powers of gases such as water vapor, "carbonic acid" (now known as carbon dioxide), ozone, and hydrocarbons. Among his most important discoveries were the vast differences in the abilities of "perfectly colorless and invisible gases and vapors" to absorb and transmit radiant heat. He noted that oxygen, nitrogen, and hydrogen are almost transparent to radiant heat while other gases are quite opaque.

Tyndall's experiments also showed that molecules of water vapor, carbon dioxide, and ozone are the best absorbers of heat radiation, and that even in small quantities, these gases absorb much more strongly than the atmosphere itself. He concluded that among the constituents of the atmosphere, water vapor is the strongest absorber of radiant heat and is therefore the most important gas controlling Earth's surface temperature. He said, without water vapor, the Earth's surface would be "held fast in the iron grip of frost." He later speculated on how fluctuations in water vapor and carbon dioxide could be related to climate change.

Tyndall related his radiation studies to minimum nighttime temperatures and the formation of dew, correctly noting that dew and frost are caused by a loss of heat through radiative processes. He even considered London as a "heat island," meaning he thought that the city was warmer than its surrounding areas.

Over the course of his life, John Tyndall published numerous papers and essays on his scientific discoveries, as well as literature, religion, mountaineering, and travel. His accomplishments led him to receive five honorary doctorates and become a respected member of thirty-five scientific societies.

J.M.I.

TYROSINE. See **Amino Acids**.

TYUYANUNITE. An ore of uranium with the composition, $Ca(UO_2)_2 (VO_4)_2 \cdot 5 - 8H_2O$, which occurs in yellow incrustations as a secondary mineral. The mineral is orthorhombic. It occurs as a secondary mineral as incrustations on limestones, and as disseminated impregnations in sandstones. Found abundantly in the Western United States, at Grants, New Mexico, and in Wyoming, Utah, Colorado, Nevada, Arizona and Texas. Also at Tyuya Muyan in Turkestan, the former U.S.S.R.

U

UGRANDITE. A group name for the calcium garnet minerals uvarovite, grossular, and andradite.

UINTAHITE. A black, shiny asphaltite, with a brown streak and conchoidal fracture, which is soluble in turpentine. It occurs primarily in the veins in the Uintas Basin, Utah.

ULEXITE. This mineral, a hydrated borate of sodium and calcium, $NaCaB_5O_9 \cdot 8H_2O$, is a product of crystallization in arid regions from shallow playas and lakes. Ulexite crystallizes in the triclinic system, but usually occurs in rounded masses of fine-fibered acicular crystals. The hardness is 2.5, specific gravity, 1.96, silky luster and white color. The mineral is found abundantly in Chile and Argentina and in Nevada and California in the United States. Ulexite is a source of boron.

ULMIN. One of a class of amorphous substances resulting from the decomposition of the cellulose and lignite tissues of plants. Ulmins represent on of the initial changes by which vegetable matter is converted into coal.

ULTRABASIC. A term proposed by Judd, in 1881, for exceedingly mafic igneous rocks composed largely, if not entirely, of the ferromagnesium minerals such as olivine and pyroxene. The limiting figure of total silica is approximately 45%, or barely sufficient to supply the needs of the basic silicates.

ULTRACENTRIFUGE. A high speed rotational separating device, usually of laboratory size, capable of developing a force of 250,000 times gravity. Its major uses are in research on molecular weight distribution, macromolecular structure and properties (proteins, nucleic acids, viruses) and separation of solutes from solutions. See also **Centrifugation**.

ULTRAFILTRATION. Ultrafiltration is a pressure-driven filtration separation occurring on a molecular scale. See also **Dialysis**; **Filtration**; **Hollow-Fiber Membranes**; **Membrane Separations Technology**; and **Reverse Osmosis**. Typically, a liquid including small dissolved molecules is forced through a porous membrane. Large dissolved molecules, colloids, and suspended solids that cannot pass through the pores are retained.

Ultrafiltration separations range from ca 1 to 100 nm. Above ca 50 nm, the process is often known as microfiltration. Below ca 2 nm, interactions between the membrane material and the solute and solvent become significant. That process, called reverse osmosis or hyperfiltration, is best described by solution–diffusion mechanisms.

Membrane-retained components are collectively called concentrate or retentate. Materials permeating the membrane are called filtrate, ultrafiltrate, or permeate.

Media

Most ultrafiltration membranes are porous, asymmetric, polymeric structures produced by phase inversion, i.e., the gelation or precipitation of a species from a soluble phase. See also **Membrane Separations Technology**. Membrane structure is a function of the materials used (polymer composition, molecular weight distribution, solvent system, etc) and the mode of preparation (solution viscosity, evaporation time, humidity, etc.). Commonly used polymers include cellulose acetates, polyamides, polysulfones, dynels (vinyl chloride–acrylonitrile copolymers) and poly(vinylidene fluoride).

Modification of the membranes affects the properties. Cross-linking improves mechanical properties and chemical resistivity. Fixed-charge membranes are formed by incorporating polyelectrolytes into polymer solution and cross-linking after the membrane is precipitated, or by substituting ionic species onto the polymer chain (e.g., sulfonation). Polymer grafting alters surface properties. Enzymes are added to react with permeable species and reduce fouling.

Polyelectrolyte complex membranes are phase-inversion membranes where polymeric anions and cations react during the gelation. Inorganic ultrafiltration membranes are formed by depositing particles on a porous substrate. Dynamic membranes are concentration–polarization layers formed *in situ* from the ultrafiltration of colloidal material analogous to a precoat in conventional filter operations. Track-etched membranes are made by exposing thin films (mica, polycarbonate, etc.) to fission fragments from a radiation source.

Process

Pore-flow models most accurately describe ultrafiltration processes. Other membrane transport mechanisms, which may occur simultaneously although generally at a much lower rate, include dialysis (diffusion), osmosis (solvent by osmotic gradient), anomalous osmosis (osmosis with a charged membrane), reverse osmosis (solvent by pressure gradient larger and opposite to osmotic gradient), electrodialysis (solute ions by electric field), piezodialysis (solute by pressure gradient), electroosmosis (solvent in electric field), Donnan effects, Knudsen flow, thermal effects, chemical reactions (including facilitated diffusion), and active transport.

When pure water is forced through a porous ultrafiltration membrane, Darcy's law states that the flow rate is directly proportional to the pressure gradient:

$$J = \frac{V}{A \cdot t} = \frac{K_m \Delta P}{\mu} \tag{1}$$

where J is permeate flux in units of volume V per membrane area A, at time t, K_m is the membrane hydraulic permeability, μ is the fluid viscosity, and ΔP is the membrane pressure drop between the retentate and permeate. These parameters change with the membrane pressure history.

The addition of small membrane-permeable solutes to the water affects permeate transport in the following ways. (*1*) Solute–solvent interactions change the permeating fluid viscosity. (*2*) Solute adsorption reduces the apparent membrane-pore diameter. Because of high interfacial tension between water and certain materials, the water phase in the pores can be replaced. Surfactants suppress hydrophobic adsorption. Adsorption of permeate species is characterized by a lag in permeate concentration as a function of time. (*3*) The interfacial charge between the membrane-pore wall and the liquid affects permeate transport when the Debye screening length approaches (ca 10%) the membrane-pore size. (*4*) High surface tension on hydrophobic membranes forces water molecules to form large clusters in the pores. (*5*) Solvents, swelling agents, and plasticizers that diffuse into the polymer structure can change the apparent pore size (K_m in eq. 1) or increase the rate of long-term compaction. The rejection R of a solute is defined as:

$$R = 1 - \frac{C_{pi}}{C_{bi}} \tag{2}$$

where C_p is the permeate concentration of species i and C_b is the concentration of that species in the retentate. There are two components of rejection. Observed rejection, R_o, is based on the concentration of the solute in the bulk solution, C_b. The intrinsic rejection, R_i, is based on the concentration of the solute on the surface of the membrane, C_w.

$$R_o = 1 - \frac{C_p}{C_b}$$

$$R_i = 1 - \frac{C_p}{C_w}$$

If the solute size is approximately the (apparent) membrane-pore size, it interferes with the pore dimensions. The solute concentration in the

permeate first increases, then decreases with time. The point of maximum interference is further characterized as a minimum flux. If the solute size is greater than the pore dimensions, the solute is retained by mechanical sieving, forming a gel-polarization layer.

The gel usually has a much lower hydraulic permeability and smaller apparent pore size than the underlying membrane. (The gel layer and the concentration gradient between the gel layer and the bulk concentration are called the gel-polarization layer.)

The gel-layer thickness is limited by mass transport back into the solution bulk at the rate. At steady state,

$$JC_b = K\frac{dC}{dX} \tag{3}$$

where C_b is the bulk concentration of all retained species. Integration gives

$$J = K \cdot \ln\frac{C_g}{C_b} \tag{4}$$

In a static system, the gel-layer thickness rapidly increases and flux drops to uneconomically low values.

The gel-polarization layer has an hydraulic permeability of K_g. Equation 4 states that flux is independent of pressure, and K_g must therefore decrease with increasing pressure. Equation 1 becomes

$$J = \frac{\Delta P}{\mu\left(\dfrac{1}{K_m} + \dfrac{1}{K_g}\right)} = \frac{\Delta P}{\mu(R_m + R_g)} \tag{5}$$

where R_m and R_g are the hydraulic resistances of the membrane gel.

Flux is independent of pressure when the process flux is much less than the wafer flux ($K_g \ll K_m$). If $K_g > K_m$, the process is limited by the membrane water flux and flux would flatten out at low concentrations of solids.

Fouling. If the gel-polarization layer is not in hydrodynamic equilibrium with the fluid bulk, the membrane may be fouled. Fouling is caused either by adsorption of species on the membrane or on the surface of the pores, or by deposition of particles on the membrane or within the pores. Fouled systems are characterized as follows: flux is a function of total permeate production when hydrodynamic conditions are constant; if hydrodynamic conditions are changed, hydraulic permeability response of the gel layer is not reversible; and theoretical permeate flux (TPF) changes with time. A sensitive test for predicting fouling or process instability is to measure change in TPF after subjecting the system to process extremes.

Fouling is controlled by selection of proper membrane materials, pretreatment of feed and membrane, and operating conditions. Control and removal of fouling films is essential for industrial ultrafiltration processes.

When fouling is present or possible, ultrafiltration is usually operated at high liquid shear rates and low pressure to minimize the thickness of the gel polarization layer.

Cleaning. Fouling films are removed from the membrane surface by chemical and mechanical methods. Dissolved fouling material may pass into the membrane pores. Reprecipitation upon rinsing must be avoided. Membrane-swelling agents, such as hypochlorites, flushout material which may be lodged in the pores.

Certain applications require that the equipment meet FDA and USDA sanitary requirements. These requirements ensure that the products are not contaminated by extractables or microorganisms from the equipment. Special considerations are given to the design of such equipment.

Practical Aspects

The theoretical models cannot predict flux rates. Plant-design parameters must be obtained from laboratory testing, pilot-plant data, or in the case of established applications, performance of operating plants.

Flux is maximized when the upstream concentration is minimized. For any specific task, therefore, the most efficient (minimum membrane area) configuration is an open-loop system where retentate is returned to the feed tank. When the objective is concentration (e.g., enzyme), a batch system is employed. If the object is to produce a constant stream of uniform-quality permeate, the system may be operated continuously (e.g., electrocoating).

Open-loop systems have inherently long residence times which may be detrimental if the retentate is susceptible to degradation by shear or microbiological contamination. A feed-bleed or closed-loop configuration is a one-stage continuous membrane system. At steady state, the upstream concentration is constant at C_f. For concentration, a single-stage continuous system is the least efficient (maximum membrane area).

The single-pass system and the staged cascade have high flux at low residence time. Both trade the concentration dependence of the batch system on time for concentration dependence on position in the system. Thus, a uniform flux is maintained (assuming no fouling) allowing continuous process integration. In practice, the single-pass system is difficult to implement, and therefore most commercial systems are multistaged cascade. The more stages used, the closer the average flux approaches the batch flux.

Electroultrafiltration

Electroultrafiltration (EUF) combines forced-flow electrophoresis. See also **Electrophoresis** with ultrafiltration to control or eliminate the gel-polarization layer. Placing an electric field across an ultrafiltration membrane facilitates transport of retained species away from the membrane surface. Thus, the retention of partially rejected solutes can be dramatically improved. See also **Electrodialysis**.

Electroultrafiltration has been demonstrated on clay suspensions, electrophoretic paints, protein solutions, oil–water emulsions, and a variety of other materials.

Diafiltration

Diafiltration is an ultrafiltration process where water or an aqueous buffer is added to the concentrate and permeate is removed. The two steps may be sequential or simultaneous. Diafiltration improves the degree of separation between retained and permeable species.

Constant-volume batch diafiltration is the most efficient process mode. Sequential batch diafiltration is a series of dilution–concentration steps. Continuous diafiltration practiced in one or more stages of a cascade system has the same volume turnover relationship for overall recoveries as sequential batch diafiltration. The residence time however is dramatically reduced. If recovery of permeable solids is of primary importance, the permeate from the last stage may be used as diafiltration fluid for the previous stage. This countercurrent diafiltration arrangement results in higher permeate solids at the expense of increased membrane area.

Membrane Equipment

Commercial industrial ultrafiltration equipment first became available in the late 1960s. Since that time, the industry has focused on five different configurations.

Parallel-Leaf Cartridge. A parallel-leaf cartridge consists of several flat plates, each having membrane sealed to both sides. Cartridges are inserted in series into plastic or stainless-steel tubular pressure housings of square cross section. Feed flows parallel to the leaf surface. A permeate fitting secures each cartridge to the housing wall, which allows permeate egress and facilitates sealing between concentrate, atmosphere, and permeate channels.

Plate and Frame. Plate-and-frame systems consist of plates each with a membrane on both sides.

At least one hole near the perimeter of each plate connects the flow channels from one side of the plate to the other. The membrane is sealed around the hole to isolate the permeate from the concentrate. Permeate collects in a drain grid behind the membrane and exits from a withdrawal port on the frame perimeter.

Spiral Wound. A spiral-wound cartridge has two flat membrane sheets (skin side out) separated by a flexible, porous permeate drainage material.

Supported Tube. There are three types of supported tubular membranes: cast in place (integral with the support tube), cast externally and inserted into the tube (disposable linings), and dynamically formed membranes. The most common supported tubes are those with membranes cast in place.

Self-Supporting Tubes. Depending on the membrane material and operating pressure, self-supporting tubes are less than 2-mm ID; inside diameters as small as 0.04 mm are commercially available.

A large number of fibers are cut to length, and potted in epoxy resin at each end. The fiber bundle is shrouded in a cylinder which aids in permeate collection, reduces airborne contamination, and allows back pressing of the membrane. Hollow-fiber membranes have also found use in ultrafiltration.

Each of the membrane devices may be assembled by connecting the modules into combinations of series, parallel-flow paths, or both.

TABLE 1. ULTRAFILTRATION APPLICATIONS

Application	Process
electrophoretic paint	control of properties, recovery of solids from rinse systems
dairy wheys	protein recovery, concentration, purification, diafiltration
milk	cheese and yogurt mfg, 15–20% yield improvement, standardization
oil–water emulsions	concentration
effluents of wool, yarn scouring	lanolin recovery, pollution abatement
enzymes	concentration, purification
biological reactors	antibiotic mfg, alcohol fermentation, sewage treatment
vegetable proteins	
latex concentration	
production of pure[a] water	
pulp and paper	lignosulfonate sprn from spent liquor
blood and blood products	fractionation, purification
vaccines	conc, purification
biotechnology products	conc, purification

[a] Virus-free.

These assemblies are connected to pumps, valves, tanks, heat exchangers, instrumentation, and controls to provide complete systems.

Because of the broad differences between ultrafiltration equipment, the performance of one device cannot be used to predict the performance of another. Comparisons can only be made on an economic basis and only when the performance of each is known.

Uses

Applications of ultrafiltration are summarized in Table 1.

ULTRAMICROSCOPE. The ultramicroscope is not an instrument of extraordinary magnifying power, as its name might suggest. The term has reference rather to a special system of illumination for very minute objects. Such objects as colloidal particles, fog drops, or smoke particles are held in liquid or gaseous suspension in an enclosure with an intensely black background (usually of the black-body type). They are illuminated by a convergent pencil of very bright light entering from one side and coming to focus in the field of view—the so-called "Tyndall cone" familiar in experiments on scattering. With this arrangement, objects too small to form visible images in the microscope produce small diffraction ring systems, which appear as minute bright specks on a dark field.

ULTRASONICS. Sound waves above the frequency normally detectable by the human ear, that is, above 16 to 20 kHz are referred to as *ultrasonic waves*. The particles of matter transmitting a *longitudinal wave* move back and forward about mean positions in a direction parallel to the path of the wave. Alternate compressions and rarefactions in the transmitting material exist along the wave propagation direction. In *shear waves*, the particles move perpendicularly to the direction of wave propagation. In *surface waves*, in seismological studies and in waves through thin stock, the *Rayleigh* and *Lamb waves*, respectively, the particles undergo much more complex vibratory motions than in longitudinal and transverse waves. In most practical applications of ultrasonics, pulses or packets containing a number of oscillation cycles are sent through the solid or liquid under investigation. See also **Cavitation**. A longitudinal wave pulse, when incident on the boundary between two materials having different sound velocities, is transformed into reflected and refracted shear and longitudinal waves. Snell's law governs the angles of reflection and refraction for both types of waves:

$$\frac{\sin\theta}{V} = \text{Constant}$$

where θ is the angle the beam makes with a plane normal to the intervening surface and V is the sound velocity. Therefore, in Fig. 1,

$$\text{Constant} = \frac{\sin\theta_1}{V_{L_1}} = \frac{\sin\theta_2}{V_{L_2}} = \frac{\sin\theta}{V_{S_2}} = \frac{\sin\phi_2}{V_{L_2}}$$

The practical application of ultrasonics requires effective transducers to change electrical energy into mechanical vibrations and vice versa. Transducers are usually piezoelectric, ferroelectric, or magnetostrictive. The application of a voltage across a piezoelectric crystal causes it to deform with an amplitude of deformation proportional to the voltage. Reversal of the voltage causes reversal of the mechanical strain. Quartz and synthetic ceramic materials are used.

Ferroelectric crystals are also electrostrictive. Barium titanate, for example, has an electrical mechanical conversion efficiency about 100 times that of quartz. Unlike the piezoelectric mode of oscillation, in ferroelectric crystals, application of a voltage in either direction across the crystal causes expansion of the crystal. This mode, however, can be converted to the piezoelectric by biasing the expansion in one direction, either by application of a strong dc field, or more commonly by cooling the ferroelectric crystal through its Curie temperature while it is under the influence of a strong electric field (on the order of 10^6 volts/meter).

Transducer crystals are normally cut to a resonant frequency, the thickness being one-half the acoustic wavelength. A bond between the crystal transducer and the specimen matches the acoustic impedance, and carries the acoustic power into the latter. Backing layers may be fixed to the rear surface of the transducer. These layers are selected to reflect power forward into the crystal and specimen in some applications. On the other hand, they may be selected to absorb power so as not to complicate signals received in material testing applications.

Ultrasonic Applications

An appreciation of useful applications of ultrasound dates back to the development of radar and sonar in the late 1930s and early 1940s World War II era. One of the very earliest uses was for detecting flaws in materials. Today ultrasound is one of several effective methods used in the field of nondestructive testing and inspection. Later, the use of ultrasound was extended to include a number of detectors, probes, and transducers for measuring such variables as fluid flow, liquid level, viscosity, density, proximity, and material thickness, among others. Most of these applications are described in other articles in this encyclopedia, notably **Nondestructive Testing (NDT)**, and Ultrasonic devices also are used in industrial processing applications, such as cleaning, drilling, emulsifying, soldering, and welding. Possible the most noteworthy of ultrasonic devices are found in the medical field for use in diagnostics where ultrasound vies with x-ray and other diagnostic procedures. Ultrasound is also applied in some security systems to detect intruders.

Ultrasonic Density Sensors. A useful application is found in the density measurement of lime slurries for the purpose of adjusting the pH in acid

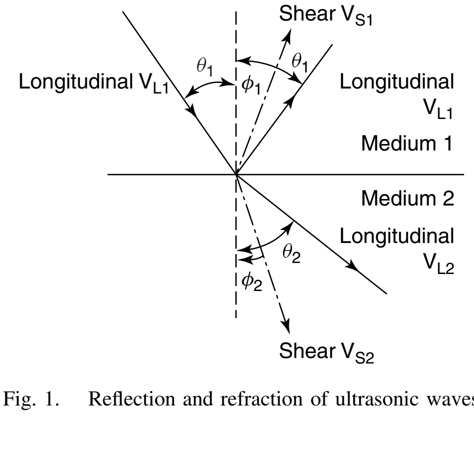

Fig. 1. Reflection and refraction of ultrasonic waves

water neutralization processes. Where traditional measurement methods are not suited, control engineers will often turn to more sophisticated techniques, such as ultrasound.

Slurries are difficult to handle, have a strong tendency to settle out and to coat equipment with which they come in contact. An ultrasonic density control sensor can be fully immersed in an agitated slurry, thus avoiding coating and clogging. Use of the ultrasound device for controlling the specific gravity of slurries within ±0.01% of the desired value has been demonstrated. In the usual application, the specific gravity ranges between 1.05 and 1.10. Actually, the ultrasonic sensor measures the percentage of suspended solids in the slurry, thus providing a very close approximation of the true specific gravity. The suspended solids present in the slurry attenuate the ultrasonic beam, with the resulting electronic signal being proportional to the solids in suspension.

Ultrasonic Level Detectors. In the ultrasound system shown in Fig. 2, one transmitting sensor creates a sonic beam, the waves of which are picked up by a receiving sensor. This can be accomplished by a direct path or by the reflective waves from the transmitter, which strike a fluid surface and are reflected back to the receiving sensor. Sensors can be spaced as close as $\frac{1}{4}$ in. (6 mm) or as far apart as 10 ft (3 m) in a direct beam path. They can pipe their beams through tubing where sensor beams cannot be direct, but generally the tubing length is limited to several feet (few meters). The sensor's sound beam is unaffected by mist, smoke, dust, or fumes, since it is interrupted only by a solid or fluid entering the beam path. This type of system is often used in connection with measuring the level of dry bulk solids.

Ultrasonic Thermometers. These are usually designed to respond to the temperature dependence of sound speed. In special cases where only one particular temperature is of interest, such as the temperature of a phase change, or the recrystallization temperature of a substance, the temperature dependence of attenuation may be utilized. Ultrasonic thermometers have found applications in the range −80 to +250°C, where the so-called quartz thermometer offers resolution of 0.1 millidegree and linear superiority to platinum resistance thermometers.

Ultrasonic Pressure Transducers. Advantage is taken of the fact that pressure influences sound propagation in solids, liquids, and gases, but in different ways. In solids, applied pressure leads to so-called stress-induced anisotropy. In liquids, the effects of pressure are usually small (relative to effects in gases), but the frequency of relaxation peaks can be shifted significantly.

Sonochemistry. Where liquids and solids must react, researchers are finding that energy in the ultrasound range often promotes such reactions. K.S. Suslick (University of Illinois), who has pioneered in the field,

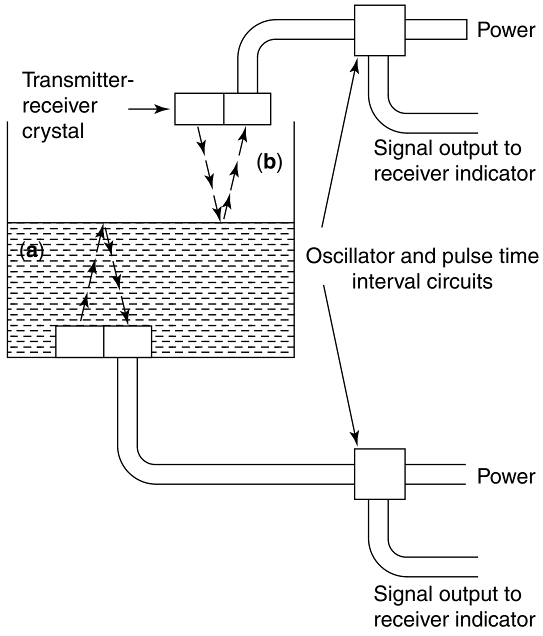

Fig. 2. Continuous sonic-type level measuring device: (**a**) Liquid phase; (**b**) vapor phase

observes, "Ultrasound causes high-energy chemistry. It does so through the process of acoustic cavitation; the formation, growth and implosive collapse of bubbles in a liquid. During cavitational collapse, intense heating of the bubbles occurs. These localized hot spots have temperatures of roughly 5000°C, pressures of about 500 atmospheres, and lifetimes of a few microseconds. Shock waves from cavitation in liquid-solid slurries produce high-velocity interparticle collisions, the impact of which is sufficient to melt most metals." In recent research, Suslick also reports that ultrasound creates clean, highly reactive surfaces on metals. In both homogeneous and heterogeneous situations, ultrasound assists in initiating and enhancing a number of catalytic reactions.

In investigating the phenomenon of acoustic cavitation in homogeneous liquids, researchers find that the velocity of sound in liquids typically is about 1500 m/s. Ultrasound spans the frequencies of approximately 15 kHz to 10 MHz, with acoustic wavelengths of 10 to 0.01 cm. Researchers in sonochemistry stress that these are not molecular dimensions and thus no direct coupling of the acoustic field with chemical species takes place on a molecular level. Rather, the effects of ultrasound arise from a number of physical mechanisms, including the production of cavitation. Cavitation, originally investigated by Lord Rayleigh (1895), can produce inordinate local temperatures of 10,000 K and pressures up to 10,000 atmospheres when cavities collapse. These physical parameters indeed are conducive to promoting chemical reactivity. Considerable research over the years has been directed toward investigating the chemical effects of ultrasound on inorganic liquids, notably water. Little effort to date has been directed toward organic liquids.

In his summary of an excellent review article on sonochemistry (reference listed), Suslick points out, "Chemical applications of ultrasound are just beginning to emerge. The very high temperatures and very short times of cavitational collapse makes sonochemistry a unique interaction of energy and matter. In addition, ultrasound is well suited to industrial applications. Since the reaction liquid itself carries the sound, there is no barrier to its use with large volumes. In fact, ultrasound is already heavily used industrially for the physical processing of liquids, such as emulsification, solvent degreasing, solid dispersion, and sol formation. It is also extremely important in solids processing, including cutting, welding, cleaning and precipitation." See also **Cavitation**.

Ultrasonic Nondestructive Characterization (NDC) of Materials. The use of ultrasonics for the nondestructive characterization (testing) of metals and other materials was one of the first practical applications for ultrasound and dates back to the 1950s. The detailed properties of materials that can be measured with ultrasound include microstructure, surface characteristics, elastic properties, density, porosity, mechanical properties, process characteristics, and overt flaws. Ultrasound waves transmitted may take the form of longitudinal, shear, and surface waves. Wave characteristics include ultrasonic velocities and frequency dependence of ultrasonic attenuation/absorption. Specific reactions occurring within a tested material may include ultrasound reflection, transmission, refraction, diffraction, interference, scattering, and absorption. In applying ultrasound to testing, the characteristics of the radiation source that can be manipulated include wave type, frequency, bandwidth, pulse shape, and pulse size.

By comparison with other NDC methods, such as liquid penetrant examination, magnetic particle, eddy current testing, and radiography, the ultrasonic method is the only technique that is applicable to a wide range of materials.

The success of an ultrasonic NDC application depends upon the selection of the best-qualified transducer (i.e., one with optimum frequency response, pulse width and shape). Transducer characteristics can be customized through the use of the best-suited piezoelectric material, such as lead zirconate-lead titanate, lead metaniobates, polymer piezoelectrics, and other advanced ferro-electric materials.

Other Transducers. Ultrasound also has been used for the measurement of force, vibration, acceleration, interface location, position changes, differentiation between the composition of differing materials, grain size in metals, and evaluation of stress and strain and elasticity in materials. Sonic devices can used to detect gas leaks, and to count discrete parts by means of an interrupted sound beam. Frequently, an ultrasonic device can be applied where photoelectric devices are used. Particularly in situations where light-sensitive materials are being processed (hence presence of light must be avoided), ultrasonic devices may be the detectors of choice.

Ultrasonic Applications in Medicine

Ultrasonic imagery is one of the earlier tools used in the medical field for noninvasively probing body organs and tissues. Experience with this technique dates back at least to the 1970s.

The nonionizing character of ultrasonic radiation is particularly attractive, permitting the use of the technique repeatedly with a given patient at low risk. The sound frequency used for most diagnostic instruments ranges from 1 to 10 MHz. These frequencies are generated by piezoelectric transducers that reversibly convert electrical to vibratory mechanical (sound) energy. Short sound pulses propagate through the body, but a small portion of the energy is reflected back to the instrument where there are interfaces between tissues having different acoustic impedances.

Ultrasonic examination has become a well-established diagnostic tool in many abdominal diseases. In recent years, the degree of resolution attainable with ultrasonic equipment has been improved considerably, making more accurate diagnoses possible. As a consequence, transabdominal sonography has become increasingly important for diagnosing diseases of the gastrointestinal tract. It is noteworthy to observe that even acute appendicitis usually can be diagnosed by ultrasonic examination.

As noted by B. Limberg (University of Frankfurt), "With the use of sonography alone, it is impossible to detect diseases of the colon reliably, since the large bowel cannot be visualized in its entirety and detailed evaluation of wall structures and intra-aluminal lesions is difficult. The method can be improved considerably, however, by the retrograde instillation of water into the colon, a method known as *hydrocolonic sonography*. Studies have shown that this method permits not only the diagnosis of colonic tumors, but also that of inflammatory colonic diseases, such as Crohn's disease and ulcerative colitis." The detailed test of 300 patients in which conventional sonography and hydrocolonic sonography were used are given in the Limberg reference listed.

In order to facilitate surgery, preoperative imaging procedures, such as ultrasonography, computed tomography (CT), and angiography, have been used to localize the primary tumor in the case of pancreatic endocrine tumors. Because of their size, insulinomas and gastrinomas cannot be identified in up to 30% of patients. As pointed out by T. Rösch (Technical University of Munich), a large team made a comparative study involving some 37 patients. Some of the study results included: "The introduction of endoscopic ultrasonography has allowed high-resolution imaging of the pancreas that can distinguish structures as small as 2 to 3 mm in diameter. The accuracy of this procedure in diagnosing small pancreatic carcinomas has been reported to be close to 100 percent. The method also seems to be useful for the preoperative localization of small endocrine tumors of the pancreas, given the experience in this research. We report here the collective experience at six centers where endoscopic ultrasonography has been used for the preoperative localization of small tumors of the pancreas. Only patients with normal results on transabdominal ultrasonography and CT were included."

Ultrasound Assists Drug Implants. Plastic materials infused with drugs are used for a number of purposes where drugs are gradually diffused into the bloodstream. Such implants are used for contraceptions and various chemotherapies. The effects of exposure to ultrasound of biodegradable implant materials have been studied at several teaching hospitals with interesting results.

Human Perception of Ultrasonic Speech. The upper range of human air-conduction hearing has been estimated to be no higher than approximately 24,000 Hz, although there have been a conservative number of reports that indicate hearing well into the ultrasonic range, but only when signals are delivered by bone conduction. M.L. Lenhardt (Medical College of Virginia) and a team of researchers has reported that "Bone-conducted ultrasonic hearing has been found capable of supporting frequency discrimination and speech detection in normal, older hearing-impaired and profoundly deaf human subjects. When speech signals were modulated into the ultrasonic range, listening to words resulted in the clear perception of the speech stimuli and not a sense of high-frequency vibration. These data suggest that ultrasonic bone-conduction hearing has potential as an alternative communication channel in the rehabilitation of hearing disorders." Further details are given in the Lenhardt reference listed.

ULTRAVIOLET LASER CHEMISTRY. See **Photochemistry and Photolysis**.

ULTRAVIOLET RADIATION. This region of the electromagnetic spectrum is subdivided into: (1) the near-ultraviolet, 4,000 to 3,000 Å, present in sunlight, producing important biological effects, but not detectable by the human eye; (2) the middle-ultraviolet, 3,000 to 2,000 Å, not present in sunlight as it reaches the Earth's surface, but well transmitted through air; and (3) the long- or extreme-ultraviolet (XUV), 2,000 to 100 Å. The latter borders on x-radiation. The latter is also called the far-ultraviolet and it is not transmitted through air. The region between 2,000 and 1,350 Å is sometimes referred to as the Schumann region after its discoverer. The boundary between far-ultraviolet and x-rays is arbitrary.

Ultraviolet radiation is emitted by nearly all light sources to some degree. Generally, the higher the temperature of the source, or the more energetic the excitation, the shorter are the wavelengths produced. Tungsten lamps in quartz envelopes radiate in the ultraviolet in accordance with Planck's law, slightly modified by the emissivity function of tungsten. Because of its high temperature (3,800°K), the crater of an open carbon arc is an excellent source of ultraviolet radiation, extending to the air cutoff. Electrical discharges through gases produce intense ultraviolet emission, mainly in lines and bands. A widely used source is the quartz mercury arc. Magnetically compressed plasma, as produced by devices such as zeta and theta pinch and which reach an extremely high temperature, are also sources of highly ionized atoms and emission lines in the far-ultraviolet. Such radiation is also produced by a synchrotron.

Solids, liquids, and gases normally transmit effectively in the near-ultraviolet range, but become opaque in the middle or extreme ultraviolet range. For constructing lenses and prisms used in ultraviolet instruments, the unusual transmittance of crystal and fused quartz, fluorite, and lithium fluoride are an immense advantage. Gases vary considerably in their absorption characteristics. Oxygen molecules cause air to become opaque below about 1,850 Å. Molecular nitrogen is relatively transparent down to

1,000 Å. Hydrogen absorbs in the Lyman series lines, and in an ionization continuum beyond the series limit, 911.7 Å. Helium is the most ultraviolet-transparent of all gases. Absorption first takes place in the resonance lines, the longest lying at 584 Å, and in a continuum beyond the series limit, 504 Å. The more complex gaseous molecules, such as CO_2, NO, and N_2O are rather opaque throughout most of the far-ultraviolet. Water vapor commences to absorb at wavelengths below 1,850 Å.

As with all visible radiation, reflection occurs for ultraviolet. Reflectance becomes less as the wavelength decreases. Aluminum is the best reflector over much of the long-wavelength region, reaching 90% down to 2,000 Å (when the metal is properly prepared), and 80% down to 1,200 Å when the aluminum is coated with a thin layer of magnesium fluoride to prevent growth of aluminum oxide. Platinum is the best reflector below 1,000 Å, achieving 20% at 600 Å, but only about 4% at 300 Å.

The simplest way to detect and measure ultraviolet radiation is by using the fluorescence process, converting the ultraviolet into radiation that can be seen; or into the near-ultraviolet range, which can be easily photographed or measured with conventional photomultipliers. Materials used for the extreme ultraviolet include oil and sodium salicylate, the latter particularly valuable because its quantum efficiency of fluorescence is high and nearly independent of wavelength. Thus, an ordinary photomultiplier with a sodium salicylate coated glass window becomes a sensitive radiometer for use throughout the entire ultraviolet region.

Ionization chambers and Geiger counters can be used for detecting extreme ultraviolet radiation. Knowledge of the ionization efficiency of the gas makes it possible to use them for measurement of absolute energy. Ultraviolet radiation also can be detected with a thermocouple, thermopile, or bolometer.

The Sun emits strongly throughout the ultraviolet, but only the near-ultraviolet reaches the Earth's surface, wavelengths shorter than 2,900 Å being absorbed by a layer of ozone in the atmosphere. See also **Oxygen**. Possible disturbance of the ozone layer by various air-polluting chemicals is considered of major importance because of the possibility of eliminating this effect and thus exposing the Earth's surface to the shorter, more dangerous ultraviolet radiation. In addition to producing sunburn, exposure of the eye to ultraviolet can cause a painful burn of the cornea and conjunctivitis. Snow blindness is caused by reflection of intense sources of middle-ultraviolet radiation from snowfields and glaciers. Ultraviolet radiation also enters into the photochemical processes which contribute to the production of smog.

The use of ultraviolet lamps has been practiced for a number of years in some hospitals, schools, and factories to check the spread of respiratory infections, but their effectiveness is inconclusive. Possibly the most effective use of the characteristics of ultraviolet radiation is in optical and instrumentation applications. See also **Ultraviolet Spectrometers**.

For the use of ultraviolet lasers in chemistry, see also **Photochemistry and Photolysis**.

ULTRAVIOLET SPECTROMETERS. Ultraviolet instruments are based upon the selective absorbance of ultraviolet radiation by various substances. The absorbance of a substance is directly proportional to the concentration of the substance which causes the absorption in accordance with the Lamber-Beer law (or simply Beer's law):

$$A = abc = \log \frac{I_0}{I} \log \frac{1}{T}$$

where A = absorbance; a = molar absorptivity, 1/(mole)(centimeter); b = path length, centimeters; c = concentration, moles/1; I_0 = intensity of radiation striking detector with nonabsorbing sample in light path; I = intensity of radiation striking detector with concentration c of absorbing sample in light path b; and T = transmittance = I/I_0.

For the vapor phase,

$$A = \frac{abc'}{2{,}450}$$

at 25°C and 760 torr pressure, where c' = volume percent or mole percent, or

$$A = \frac{abc'}{2{,}450} \times \frac{P + 14.7}{14.7} \times \frac{298}{t + 273}$$

at any temperature or pressure, where P = pressure, psig; and t = temperature °C.

For the liquid and solid phases.

$$c = \frac{c'' \times d}{\text{M.W.}} \times 10 = \text{moles/1}$$

where c'' = weight percent in liquid; d = density of liquid; and M.W. = molecular weight of material to be measured.

$$A = \frac{10abc''d}{\text{M.W.}}$$

The fundamental elements of an ultraviolet-absorption analyzer include: (a) a radiation source; (b) suitable optical filters; (c) a sample cell; and (d) an output meter. A transmittance measurement is made by calculating the ratio of the reading of the output with the sample in the cell to the reading with the cell empty (of ultraviolet-absorbing materials). The concentration can be calculated from the known absorptivity of the substances as previously demonstrated by the equations; or it may be determined by comparison with known samples.

Sources of ultraviolet radiation include: (a) tungsten-filament incandescent lamps; (b) tungsten-iodine cycle lamps with quartz envelopes; (c) mercury-vapor lamps; and (d) the zinc discharge lamp. Other types are available, but enjoy only limited application. The hydrogen or deuterium lamps are used in the laboratory, but are delicate and costly for process uses.

The analytical radiation in an ultraviolet analyzer must be as nearly monochromatic as possible in the interest of high linearity, long-time stability, and sustained accuracy. Monochromatic radiation is obtained by proper selection of sources, filters, and phototubes, each of which is selective in regard to the wavelengths that it respectively emits, transmits, or responds to. For lenses and windows, fused quartz is the most commonly used for windows and for some lenses. Corning 7910 glass and synthetic sapphire transmit throughout the near-ultraviolet range. Mirrors of rhodium or special alloys may be less reflecting in certain regions, but are preferred over silver and aluminum because of their high resistance to scratching and corrosion. Semitransparent mirrors for beamsplitting are made of special alloys or chromium coatings evaporated upon quartz or glass.

Vacuum phototubes are preferred as detectors over barrier-layer photocells because of their higher signal-to-noise ratio, greater stability, longer life, and freedom from fatigue. Simple tubes are preferred over multiplier types because they are less costly, are more stable, and can be used in simpler circuits.

The simplest ultraviolet-absorption analyzer is the *single beam* type. The output of this type of instrument will be affected by fluctuations and drift of the light source, dirt or bubbles in the sample cell, and any drift in the detector or detector circuit. Thus, single-beam instruments operate on relatively low sensitivity (high absorbance) levels to provide reasonably stable analyses. Improved single-beam instruments have found extensive applications where only a "go-no-go" or broad range measurement will suffice. The *split-beam* analyzer overcomes most of the foregoing shortcomings and is based upon a differential absorption measurement at two wavelengths. The optical diagram of a double-beam grating ultraviolet spectrophotometer is shown in Fig. 1. Each band of wavelengths, isolated by the grating monochromator, is split into two beams, which pass alternately through the sample and reference paths. The two beams are then recombined along a single path, but separated in time. Thus, the detector receives an alternating optical signal consisting of radiant power P through the sample and P_0 through the reference. This output is converted into an electrical signal that is related to the transmittance of the sample P/P_0.

One of the more important areas of use of ultraviolet instruments is the identification and determination of biologically active substances. Many components in body fluids can be determined either directly or through colorimetric methods. Drugs and narcotics can be measured both in the body as well as in formulations. Vitamin assay is another related activity. Nearly all metals and nonmetals can be determined through their ultraviolet absorption or by colorimetric methods. In recent years, ultraviolet instruments have been used extensively for the determination of air and water pollutants, such as aldehydes, phenolics, and ozone;

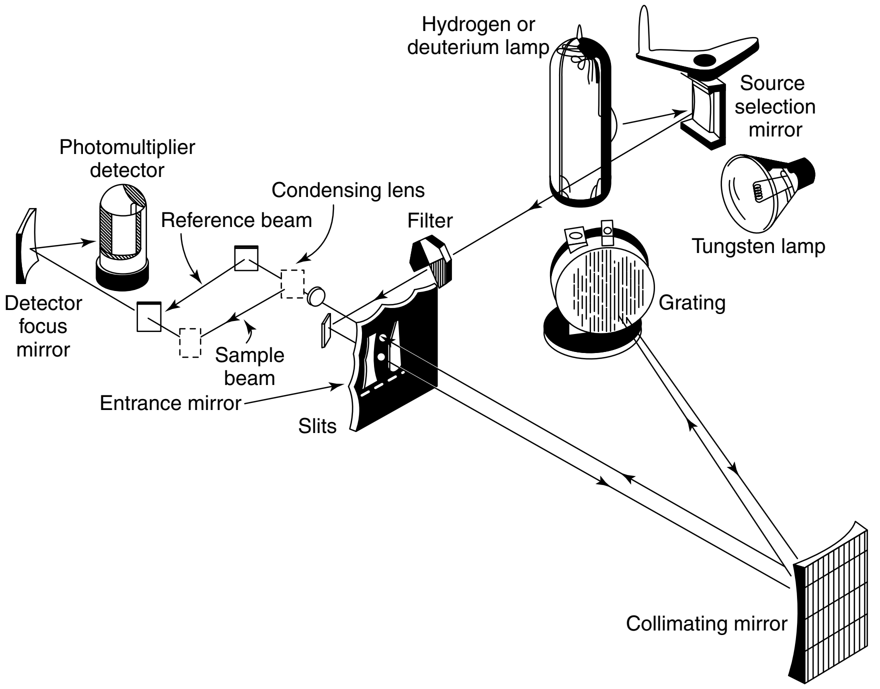

Fig. 1. Optical path of double-beam grating ultraviolet spectrophotometer. (*Beckman*)

for the analysis of dyestuffs; for studies on polyaromatics and other carcinogenic substances; for the determination of food additives; for the analysis of petroleum fractions; and for the detection and determination of pesticide residues.

ULTRAVIOLET STABILIZERS. When a polymer absorbs light, it may reradiate the absorbed energy at much longer wavelengths (heat), at slightly longer wavelengths (luminescence), or the energy may be transferred to another molecule. When none of these processes is operative, the absorbed light energy may cause bond breaking leading to degradation. By incorporating an ultraviolet absorbing compound into the plastic, it is possible to essentially eliminate all of the above processes, since the absorber even at concentrations as low as 0.5% can effectively compete for the incident ultraviolet radiation, thus protecting the plastic from degradation. A second approach to stabilization is to incorporate an additive which, though not an absorber in itself, can accept energy from the polymer substrate, and thus, leave the polymer intact. Since protection of plastics against light degradation can be achieved by these two mechanisms, the broader term *ultraviolet stabilizer* or *light stabilizer* is used to refer to such additives.

Ultraviolet absorbers continue to be the most widely used stabilizers. Such products must have long-term stability to ultraviolet light, be relatively nontoxic, heat stable, have little color, must not sensitize the substrate, and must be priced at levels which the plastics processor can tolerate. The principal classes of chemicals meeting these requirements at present are the 2-hydroxybenzophenones, and 2-(2′-hydroxyphenyl)benzotriazoles, substituted acrylates, and aryl esters. Typical compounds representative of these classes are 2-hydroxy-4-octoxybenzophenone, 2-(2′-hydroxy-5′-methylphenyl) benzotriazole, ethyl-2-cyano-3,3-diphenyl acrylate, dimethyl *p*-methoxybenzylidene malonate, and *p*-*tert*-octylphenyl salicylate.

The particular absorber to be used in a given application depends on several factors. One important criterion is whether the absorber will strongly absorb that portion of the ultraviolet spectrum responsible for degradation of the plastic under consideration. Compatibility, volatility, thermal stability, and interactions with other additives and fillers are other items that must be considered. When used in food wrappings, Food and Drug Administration approval must be obtained. While one or more of these considerations may rule out a given stabilizer or influence the choice of one class over another, the final selection must await the results of extensive accelerated and long-term tests.

At this point, it should be indicated that much effort has gone into the development of accelerated testing procedures. Many of the devices and techniques employed are based on knowledge gained in the evaluation of dyes, textiles, and rubber. For example, the carbon-arc Fade-O-Meter and the Xenon-arc Weather-O-Meter have been adapted from the dye field for use in plastics evaluation. Extensive use is also made of the fluorescent sunlamp, fluorescent blacklight, S-1 sunlamp, Hanovia lamp, and others. Such instruments are very useful for comparison of one stabilizer with others and for evaluating total stabilizing formulations in particular polymers. Nevertheless, no accelerated weathering device has yet been found which can accurately predict the outdoor weatherability of a broad range of polymers. Accelerated outdoor weathering is carried out in Phoenix, Arizona, where high levels of ultraviolet radiation occur and the temperature is high. To determine the lifetime under more humid conditions, tests are often conducted in the vicinity of Miami, Florida.

For extended outdoor applications, most polymers require some degree of light stabilization. There are wide variations in the inherent stability of different polymers ranging from less stable ones, such as polypropylene, to the highly light-stable poly(methyl methacrylate). Because of the dramatic growth of polyolefins, and particularly polypropylene, over the past several years, there has been an upsurge in requirements for ultraviolet absorbers. The hydroxybenzophenones, such as 2-hydroxy-4-octoxy benzophenone, have been widely used for stabilization of polypropylene. The benzotriazoles have also achieved commercial importance in this application. End uses of polypropylene requiring ultraviolet absorbers include upholstery fabrics, indoor-outdoor carpeting, lawn furniture, ropes, and various crates and boxes. Polyethylene is also stabilized with the hydroxy benzophenone absorbers. Applications include baskets, beverage cases, bags for fertilizer, and films for greenhouses.

Polystyrene light stabilization has been achieved with a variety of ultraviolet absorbers including the benzophenones, benzotriazoles, and salicylates. While yellowing of polystyrene occurs in many applications, it is particularly noticeable in diffusers used with fluorescent lights. This problem has been effectively solved by using ultraviolet light absorbers. In this instance, superior stabilization is achieved when the ultraviolet absorber is used in conjunction with specific antioxidants.

The hydroxybenzophenones, hydroxyphenylbenzotriazoles, and substituted acrylates are all used for stabilization of polyvinyl chloride. This polymer is growing at a substantial rate, and increasing uses are developing for light-stabilized grades. Among current uses, may be mentioned auto seat covers, floor tiles, light diffusers, vinyl-coated fabrics, siding, and exterior trim. Since the processing of polyvinyl chloride requires the use of a heat stabilizer, care must be exercised to avoid undesirable interactions between the heat and light stabilizers.

The stabilization of polyesters is generally achieved with the hydroxybenzophenone and hydroxyphenylbenzotriazole absorbers. The choice of absorber depends on the curing catalysts and promoters used. The stabilization of fire retardant grades of polyesters offers a greater problem than the standard grades because the halogenated monomer acids used are appreciably more sensitive to ultraviolet light than the unhalogenated acids (phthalic, isophthalic). Applications for light-stabilized polyesters include sheets for roofs and skylights and various surface coatings.

Cellulosic plastics are used in a number of outdoor applications with signs being one of the principal areas of use. This plastic can be stabilized reasonably well with the aryl esters of salicyclic acid. It is of interest to note that these esters undergo a photochemical rearrangement in the plastic to derivatives of hydroxy benzophenone. The hydroxy benzophenones may be added initially to effect stabilization.

As noted earlier, poly(methyl methacrylate) plastic has excellent resistance to ultraviolet radiation. Nevertheless, in long-term outdoor applications or in lighting fixtures, small amounts of ultraviolet absorbers are employed to retard the yellowing and degradation in physical properties which would otherwise occur.

The previous discussion illustrates how widely ultraviolet absorbers are used for stabilization of plastics against degradation by ultraviolet light. The second principal method for light stabilization is the use of energy transfer agents. Important stabilizers currently in use which function by this mechanism are nickel complexes of 2, 2′-thiobis(4-*tert*-octylphenol). For example, the butyl amine adduct of this complex is widely used. The nickel salts of mono alkyl esters of 3,5-di-*tert*-butyl-4-hydroxybenzyl phosphonic acid are also useful stabilizers. When color is not a consideration, nickel dialkyl dithiocarbamates, and nickel acetophenone oximes may be used. Thus far, the nickel stabilizers have been used primarily in polypropylene and to some extent in polyethylene. They are especially useful in polypropylene fibers since stabilization by energy transfer is less dependent on sample thickness than is stabilization by ultraviolet absorption. Some of the nickel stabilizers have the further advantage that they act as dye acceptors and thus aid printing and dyeing of fibers and other items made from polyolefins.

Thus far, the discussion on ultraviolet stabilizers has been concerned only with their use for stabilization of plastics. While this is the principal use, the stabilizers which function by absorption are also widely used to prevent ultraviolet light from damaging furniture, clothing, and other articles. For example, a thin plastic film (6–10 mil) containing a high concentration of absorber is useful for covering a store window exposed to the sun. Such a film absorbs the ultraviolet radiation and thus prevents damage to the articles behind the film. The clarity and lack of color of the film permits customers to see the articles readily. Surface coatings containing ultraviolet absorbers are used in the same way to protect items such as flooring and furniture. Ultraviolet absorbing coatings may also be used to protect plastics, but generally, it is more practical to incorporate the absorber in the plastic itself. The incorporation of ultraviolet absorbers into plastic sunglasses is important for protecting the eye from ultraviolet radiation damage. Suntan lotions contain compounds such as monoglyceryl *p*-aminobenzoate that permit the longer wave lengths (330–400 nm) in the ultraviolet which cause tanning to pass through to the skin. At the same time, the more highly energetic short wave lengths (290–330 nm) which cause burning are strongly absorbed. When no tanning is desired, creams containing hydroxy benzophenones may be used, since these products remove a high percentage of the 290–400 nm radiation.

Highly satisfactory formulations have been developed for light stabilization of a wide range of polymers. Studies are continuing not only toward empirical development of superior stabilizing formulations, but also toward understanding the mechanisms of the degradation and inhibition process involved. This dual approach can be expected to yield products which will meet the increasingly severe demands that will result as plastics find their way into new outdoor uses.

American Cyanamid Co.
Bound Brook, New Jersey

UNCERTAINTY PRINCIPLE. Also sometimes referred to as the *indeterminancy principle*, this was first stated by Heisenberg, Werner P, in connection with the position and momentum of an electron. In essence, the postulate states that it is impossible to determine simultaneously both the exact position and the exact momentum of an electron and thus these values must be expressed as a probability. If, for example, one determines the precise location of an electron, all information about the electron's velocity is lost. On the other hand, knowledge of the electron's velocity can be obtained only at the expense of knowledge of its location.

Classical Newtonian mechanics assumes that a physical system can be kept under continuous observation without thereby disturbing it. This is reasonable when the system is a planet or even a spinning top, but is unacceptable for microscopic systems, such as an atom. To observe the motion of an electron, it is necessary to illuminate it with light of ultrashort wavelength (gamma rays); momentum is transferred from the radiation to the electron and the particle's velocity is, therefore, continuously disturbed. The effect upon a system of observing it can not be determined exactly, and this means that the state of a system at any time cannot be known with complete precision. As a consequence, predictions regarding the behavior of microscopic systems have to be made on a probability basis and complete certainty can rarely be achieved. This limitation is accepted and is made one of the foundation stones upon which the theory of quantum mechanics is constructed.

This principle can be extended to other phenomena of a like nature, that is, in the simultaneous determination of the values of two canonically conjugated variables, the product of the smallest possible uncertainties in their values is of the order of magnitude of the Planck constant h. If Δq is the range of values that might be found for the coordinate q of a particle, and Δp is the range in the simultaneous determination of the corresponding component of its momentum p, then $\Delta p \cdot \Delta q \geq h$. Similarly, if ΔE and Δt are the uncertainties in the simultaneous determination of the energy and the time, $\Delta E \cdot \Delta t \geq h$. In the same way, the principle applies to any other pair of canonically conjugated variables. See also **Quantum Mechanics**.

UNITS AND STANDARDS. The General Conference on Weights and Measures, to which the United States adheres by treaty, has established the International System of Units, called SI units. The base quantities of this system and the corresponding units and symbols are:

Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Luminous intensity	candela	cd
Amount of substance	mole	mol

The units radian (rad) for plane angle and steradian (sr) for solid angle are described as supplementary units and are normally treated as though they were base units, although the corresponding quantities may be treated as dimensionless. The coherent SI unit system consists of the foregoing, plus all of the units derived from them by multiplication and division without introducing numerical factors.

TABLE 1. UNITS DERIVED FROM BASE SI QUANTITIES

Quantity	Name of SI derived unit	Symbol	Expressed in terms of SI base or derived units
frequency	hertz	Hz	$1\ \mathrm{Hz} = 1\ \mathrm{s}^{-1}$
force	newton	N	$1\ \mathrm{N} = 1\ \mathrm{kg \cdot m/s^2}$
pressure and stress	pascal	Pa	$1\ \mathrm{Pa} = 1\ \mathrm{N/m^2}$
work, energy, quantity of heat	joule	J	$1\ \mathrm{J} = 1\ \mathrm{N \cdot m}$
power	watt	W	$1\ \mathrm{W} = 1\ \mathrm{J/s}$
quantity of electricity	coulomb	C	$1\ \mathrm{C} = 1\ \mathrm{A \cdot s}$
electromotive force, potential difference	volt	V	$1\ \mathrm{V} = 1\ \mathrm{W/A}$
electric capacitance	farad	F	$1\ \mathrm{F} = 1\ \mathrm{A \cdot s/V}$
electric resistance	ohm	Ω	$1\Omega = 1\ \mathrm{V/A}$
electric conductance	siemens	S	$1\ \mathrm{S} = 1\Omega^{-1}$
flux of magnetic induction, magnetic flux	weber	Wb	$1\ \mathrm{Wb} = 1\ \mathrm{V \cdot s}$
magnetic flux density, magnetic induction	tesla	T	$1\ \mathrm{T} = 1\ \mathrm{Wb/m^2}$
inductance	henry	H	$1\ \mathrm{H} = 1\ \mathrm{V \cdot s/A}$
luminous flux	lumen	lm	$1\ \mathrm{lm} = 1\ \mathrm{cd \cdot sr}$
illuminance	lux	lx	$1\ \mathrm{lx} = 1\ \mathrm{lm/m^2}$

UNITS, NOT PART OF COHERENT SYSTEM, BUT GENERALLY ACCEPTED FOR USE WITH SI UNITS

Quantity	Name of unit	Unit symbol	Magnitude in SI units
time	minute	min	60 s
	hour	h	3600 s
	day	d	86400 s
plane angle	degree	°	$\pi/180$ rad
	minute	′	$\pi/10\ 800$ rad
	second	″	$\pi/648\ 000$ rad
Volume	litre	L	$1\ l = 1\ dm^3$
mass	tonne	T	$1\ t = 10^3$ kg
energy	electronvolt	eV	approx. 1.60219×10^{-19} J
mass of an atom	atomic mass unit	u	approx. 1.66053×10^{-27} kg
length	astronomical unit	AU	149600×106 m
	parsec	pc	approx. 30857×1012 m

TABLE 2. STANDARD PREFIXES USED WITH SI UNITS

Factor by which the unit is multiplied	Prefix name	Symbol
10^{12}	tera	T
10^9	giga	G
10^6	mega	M
10^3	kilo	k
10^2	hecto	h
10	deca	Da
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	Micro	m
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	Femto	f
10^{-18}	atto	a

TABLE 3. PRINCIPAL UNITS—SYMBOLS, DEFINITIONS, DIMENSIONS

AMPERE (A). *The constant current that, if maintained in two straight parallel conductors that are of infinite length and negligible cross section and are separated from each other by a distance of 1 meter in a vacuum, will produce between these conductors a force equal to* 2×10^{-7} *newton per meter of length*. (The SI unit of electric current.)

AMPERE PER METER (A/m). *The magnetic field strength in the interior of an elongated uniformly wound solenoid which is excited with a linear current density in its winding of 1 ampere per meter of axial distance*. (The SI unit of magnetic field strength.)

AMPERE-HOUR (Ah). *The quantity of electricity represented by a current of 1 ampere flowing for 1 hour*.

ANGSTROM Å. *A unit of length equal to* 10^{-10} *meter*.*

APOSTILB (asb). *A unit of luminance. One lumen per square meter leaves a surface whose luminance is 1 apostilb in all directions within a hemisphere*. (The candela per square meter is the preferred unit of luminance.)

ATMOSPHERE, STANDARD (atm). *A unit of pressure. One standard atmosphere equals 101,325 newtons per square meter*.

ATOMIC MASS UNIT, UNIFIED (u). *The atomic mass unit (unified) is 1/12th of the mass of an atom of the* ^{12}C *nuclide*. (Use of the prior atomic mass unit (amu), defined by reference to oxygen, is no longer preferred.)

BAR (bar). *A unit of pressure. One bar equals 100,000 newtons per square meter*.

BARN (b). *A unit of nuclear cross section. One barn equals* 10^{-28} *square meter*.

BARREL. (bbl). *A unit of volume. One barrel equals 9,702 cubic inches; or 0.15899 cubic meters*. (This is the standard barrel used for petroleum, etc. A different standard barrel is used for fruits, vegetables, and dry commodities.)

BAUD (Bd). *A unit of signaling speed. One baud equals one element per second*. (The signaling speed in bauds is equal to the reciprocal of the signal element length in seconds.)

BEL (B). *A dimensionless unit for expressing the ratio of two values of power, being the logarithm to the base 10 of the power ratio*. (The more commonly used unit, decibel (dB), is 10 times the logarithm to the base 10 of the power ratio. A bel is 10 decibel.)

BIT (b). *A unit of information, generally represented by a pulse. A bit is a binary digit, i.e., a 1 or 0 in computer technology*. (In information theory, the bit is the smallest possible unit of information.)

BIT PER SECOND (b/s). *A unit of signaling speed. A transference rate of 1 bit per second*.

BRITISH THERMAL UNIT (Btu). *A unit of heat. The heat required to warm 1 pound of pure water through an interval of 1 degree Fahrenheit*.

CALORIE (International Table) (cal_{It}). *A unit of heat. One International Table calorie equals 4.1868 joules*. (The 9th Conférence Générale des Poids et Mesures adopted the joule as the unit of heat.)

CALORIE (Thermochemical Calorie) (cal). *A unit of heat. One calorie equals 4.1840 joules*. (See foregoing note.)

CANDELA (cd). *The luminous intensity of 1/6000,000 of a square meter of a radiating cavity at the temperature of freezing platinum (2042 K)*. (The SI unit of luminous intensity. The unit formerly was called the *candle*.)

CIRCULAR MIL (cmil). *The area of a circle whose diameter is 0.0001 inch. One circular mil equals* $\pi/4 \cdot 10^{-6}$ *square inches*.

COULOMB (C). *The quantity of electric charge which passes any cross section of a conductor in 1 second when the current is maintained constant at 1 ampere*. (The SI unit of electric charge.)

CURIE (Ci). *The unit of activity in the field of radiation dosimetry. One curie equals* 3.7×10^{10} *disintegrations per second*. (The activity of 1 gram of ^{226}Ra is slightly less than 1 curie.)

CYCLE (c). *An interval of space of time in which is completed 1 round of events or phenomena*.

CYCLE PER SECOND (Hz, c/s). *The number of cycles per second*. (The name hertz (Hz) is the accepted international term. The abbreviation Hz is preferred to c/s.)

DARCY (D). *A unit of permeability of a porous medium. One darcy equals 1 cP (cm/s)(cm/atm) equals 0.986923 square micrometers*. (A permeability of 1 darcy will allow the flow of 1 cubic centimeter per second of fluid of 1 centipoise viscosity through an area of 1 square centimeter under a pressure gradient of 1 atmosphere per centimeter.)

DAY (d). *A unit of time, the exact definition of which is dependent upon which system of time measurement is referred to, i.e., apparent solar time, mean solar time, universal time, apparent sidereal time, ephemeris time, or atomic time*. See **Time**. With exception of atomic time, the time base is referenced to rotation of the Earth. For general purposes, a day is considered the period taken for 1 revolution of the Earth about its axis.

DEGREE CELSIUS (°C). *One unit of temperature on the Celsius temperature scale*, which is derived from the thermodynamic of Kelvin scale of temperature and related by: Temperature (degrees Celsius) equals Temperature (Kelvin units) minus 273.15. See Temperature.

DEGREE FAHRENHEIT (°F). *One unit of temperature on the Fahrenheit temperature scale*, which is related to the Celsius temperature scale by: Temperature (degrees Fahrenheit) equals 1.8× (degrees Celsius) plus 32. See Temperature.

DEGREE RANKINE (°R). *One unit of temperature on the Rankine temperature scale*, which is related to the Fahrenheit temperature scale by: Temperature (degrees Rankine) equals Temperature (degrees Fahrenheit) plus 459.69. See **Temperature**.

DYNE (dyn). *A unit of force. One dyne equals the force necessary to give 1 gram mass an acceleration of 1 centimeter/(second)(second)*. (The dyne is the unit of force in the CGS system.)

ELECTRONVOLT (eV). *A unit of energy. One electronvolt equals the energy acquired by an electron when it passes through a potential difference of 1 volt in a vacuum*. (One electronvolt equals 1.602×10^{-12} erg.)

ERG (erg). *A unit of energy. One erg equals* 10^{-7} *joule*. (Also, 1 erg equals the work done when a force of 1 dyne is applied through a distance of 1 centimeter. One foot-pound equals 13,560,000 ergs.)

FARAD (F). *The capacitance of a capacitor in which a charge of 1 coulomb produces a potential difference of 1 volt between the terminals*. (The SI unit of capacitance.)

FOOTCANDLE (fc). *A unit of luminance. One footcandle equals 1 lumen per square foot*. (The name *lumen per square foot* is recommended for this unit. The SI unit, lux (lumen per square meter), is preferred.)

FOOTLAMBERT (fL). *A unit of luminance. One lumen per square foot leaves a surface whose luminance is 1 footlambert in all directions within a hemisphere*. (If luminance is measured in English units, the candela per square inch is preferred. However, use of the SI unit, the candela per square meter, is generally accepted.)

GAL (Gal). *A unit of acceleration. One Gal equals 1 centimeter per second per second*.

GALLON (gal). Because the gallon, quart, and pint differ in the United States and the United Kingdom, the use of this unit and term is generally discouraged for scientific purposes. An imperial gallon equals 1.20095 U.S. gallons. One U.S. gallon equals 3.785×10^{-3} cubic meter.

GAUSS (G). *A unit of magnetic flux density, or magnetic induction. The ratio of the flux in any cross section to the area of that cross section, the cross section being taken normal to the direction of flow. One gauss equals 1 maxwell per square centimeter*. (The gauss is a unit of the CGS system. Use of the SI unit, the *tesla*, is preferred.)

(*continued overleaf*)

TABLE 3. (*continued*)

GILBERT (Gb). *A unit of magnetomotive force. One gilbert equals 0.4 π(ni), where (ni) is an ampere-turn.* (The gilbert is a unit of the CGS system. Use of the SI unit, the ampere (or ampere-turn), is preferred.)
GRAIN (gr). *A unit of mass. One grain equals 0.06480 gram.* (One ounce, avoidupois, equals 437.5 grains; 1 ounce, troy, equals 480 grains; 1 ounce, apothecaries', equals 480 grains. One pound, avoirdupois, equals 7,000 grains.)
GRAM (g). *A unit of mass. One gram equals 1/1,000th kilogram.* (See also KILOGRAM in this list.)
HENRY (H). *A unit of inductance. The inductance of a circuit in which a current of 1 ampere induces a flux linkage of 1 weber.* (The SI unit of inductance.)
HERTZ (Hz). *A unit of frequency. One hertz equals a frequency of one cycle per second.* (The SI unit of frequency.)
HORSEPOWER (hp). The horsepower is considered an anachronism in science and technology. Use of the SI unit of power, the watt, is preferred. When used, 1 horsepower equals (1) 42.44 Btu/minute; (2) 33,000 foot-pounds/minute; or (3) 550 foot-pounds/second.
HOUR (h). *A unit of time. One hour equals 60 minutes, or 3,600 seconds.*
INCH (in). *A unit of length. One inch equals* 2.540×10^{-2} *meter.*
INCH OF MERCURY (inHg). *A unit of pressure. One inch of mercury equals 3,386.4 newtons per square miter.* (An inch of mercury also equals (1) 0.03342 atmosphere; (2) 1.133 feet of water; (3) 345.3 kilograms/square meter; (4) 70.73 pounds/square foot; or (5) 0.4912 pounds/square inch.
INCH OF WATER (in H_2O). *A unit of pressure. One inch of water equals 249.09 newtons per square meter.* (An inch of water also equals (1) 2.458×10^{-3} atmosphere; (2) 0.07355 inch of mercury; (3) 2.540×10^{-3} kilogram/square centimeter; (4) 0.5781 ounce/square inch; (5) 5.204 pounds/square foot; or (6) 0.03613 pound/square inch. The latter Figures hold for a temperature of 4°C.)
JOULE (J). *A unit of energy. The work done by 1 newton acting through a distance of 1 meter.* (The SI unit of energy. One joule equals 1 watt-second; equals 10^7 ergs; equals 10^7 dyne-centimeters.)
JOULE PER KELVIN (J/K). *A unit of heat capacity and entropy.*
KELVIN (K). *The basic unit of thermodynamic temperature. One kelvin is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.* (The term *degree Kelvin* was officially dropped in 1967. Thus, the symbol is K and not °K. Relationship of the Kelvin scale to the Celsius scale is given earlier in this list under DEGREE CELSIUS.)
KILOGRAM (kg). *A unit of mass and is based upon a cylinder of platinum-iridium alloy kept by the International Bureau of Weights and Measures at Paris.* A duplicate in the custody of the National Bureau of Standards at Washington is the mass standard for the United States. The kilogram is the only base unit still defined by an artifact. (A kilogram equals (1) 1,000 grams; (2) 2.205 pounds; (3) 9.842×10^{-4} long tons; or (4) 1.102×10^{-3} short tons.
KNOT (kn). *A unit of speed. One knot equals 1 nautical mile per hour.* (A knot also equals 6,080.2 feet/hour; or 1.151 statute miles/hour.)
LAMBERT (L). *A unit of luminance. One lumen per square centimeter leaves a surface whose luminance is 1 lambert in all directions within a hemisphere.* (The candela per square meter is the preferred unit of luminance.)
LITER (l). *A unit of volume. One liter equals* 10^{-3} *cubic meter.* (A liter also equals (1) 1,000 cubic centimeters; (2) 0.03531 cubic foot; (3) 61.02 cubic inches; (4) 1.308×10^{-3} cubic yard; (5) 0.2642 U.S. liquid gallon; (6) 1.057 U.S. liquid quarts; or (7) 0.22 Imperial gallon.
LUMEN (lm). *A unit of luminous flux. The flux through a unit solid angle (steradian) from a uniform point source of 1 candela.* (The SI unit of luminous flux.)
LUMEN PER SQUARE FOOT (lm/ft^2). *A unit of illuminance and also a unit of luminous excitation.* (Use of the SI unit, lumen per square meter, is preferred.)
LUMEN PER SQUARE METER (lm/m^2). *A unit of luminous excitation.* (The SI unit of luminous excitation.)
LUMEN PER WATT (lm/W). *A unit of luminous efficacy.* (The SI unit of luminous efficacy.)
LUMEN SECOND (lm · s). *A unit of quantity of light.* (The SI unit of quantity of light.)
LUX (lx). *A unit of illuminance. One lux equals 1 lumen per square meter.* (The SI unit of illuminance.)
MAXWELL (Mx). *A unit of magnetic flux. The flux through a square centimeter normal to a field at 1 centimeter from a unit magnetic pole.*
METER (m). *A unit of length. Defined as 1,650,763.73 wavelengths in vacuum of the orange-red line of the spectrum of* 86Kr*(krypton).* (The SI unit of length. A meter also equals (1) 100 centimeters; (2) 3.281 feet; (3) 39.37 inches; (4) 0.001 kilometer; (5) 5.396×10^{-4} nautical mile; (6) 6.214×10^{-4} statute mile; or (7) 1.094 yards.
MHO (mho). *A unit of conductance (and of admittance). The conductance of a conductor whose resistance is 1 ohm.* (The name *siemens* (S) also is used for this quantity.)

MICROMETER (μm). *A unit of length. One micrometer equals one-millionth of a meter.* (The term *micron* formerly used for this unit no longer is preferred.)
MICRON. See MICROMETER above.
MIL (mil). *A unit of length. One mil equals one-thousandth of an inch.*
MILE, STATUTE (mi). *A unit of length. One mile equals 5,280 feet.* (One statute mile also equals (1) 1.609 kilometers; (2) 1,760 yards; (3) 6.336×10^4 inches; or (4) 0.8684 nautical mile.)
MILE, NAUTICAL (nmi). *A unit of length. One nautical mile equals 1.1516 statute miles.* (One nautical mile also equals (1) 6,080.27 feet; (2) 1.853 kilometers; or (3) 2,027 yards.)
MINUTE, TIME (min). *A unit of time. One minute equals 60 seconds.* (Time also may be designated by means of superscripts, as in $9^h46^m30^s$, where there otherwise will be no confusion with abbreviations.)
MOLE (mol). A unit of amount of substance. One mole is an amount of a *substance, in specified mass units, equal to the molecular weight of that substance.* (The SI unit for amount of substance. Examples are the gram mole or the pound mole.)
NEPER (Np). A dimensionless unit for expressing the ratio of two voltages, two currents, or two power values in a logarithmic manner. The number of nepers is the natural (Napierian) logarithm of the square root of the ratio of the two values being compared. Thus, the neper uses the base of 2.71828 in contrast with the bel (or decibel) which uses the common-logarithm base of 10. One neper equals 8.686 decibels.
NEWTON (N). *A unit of force. One newton is the force that will impart an acceleration of 1 meter per second per second to a mass of 1 kilogram.* (The SI unit of force. One newton equals 10^5 dynes.)
NIT (nt). *A unit of luminance and is synonymous with candela per square meter.*
OERSTED (Oe). *A unit of magnetic field strength. The magnetic field produced at the center of a plane circular coil of 1 turn and of radius 1 centimeter, which carries a current of* $(\frac{1}{2}\pi)$ *abamperes.* (An abampere equals 10 amperes. The oersted is the CGS unit of magnetic field strength. Use of the SI unit, the ampere per meter, is preferred.)
OHM (Ω). *A unit of resistance (and of impedance). The resistance of a conductor such that a constant current of 1 ampere in it produces a voltage differences of 1 volt between its ends.* (The SI unit of resistance.)
PASCAL (Pa). *A unit of pressure or stress. One pascal equals 1 newton per square meter.*
PHON (phon). *A unit of loudness level. The pressure level in decibels of a pure* 1,000 Hz*tone.*
PHOT (ph). *A unit of illuminance. One phot equals 1 lumen per square centimeter.* (The phot is the CGS unit of illuminance. Use of the SI unit, the lux, is preferred.)
PINT (pt). Because the gallon, quart, and pint differ in the United States and the United Kingdom, the use of this unit and term is generally discouraged for scientific purposes. One U.S. pint equals: (1) 473.2 cubic centimeters; (2) 0.01671 cubic foot; (3) 28.87 cubic inches; (4) 4.732×10^{-4} cubic meter; (5) 6.189×10^{-4} cubic yard; (6) 0.125 U.S. gallon; (7) 0.4732 liter; or (8) 0.5 liquid U.S. quart.
POISE (P). A unit of dynamic viscosity. The unit is expressed in dyne second per square centimeter. The centipoise (cP) is more commonly used. The formal definition of viscosity arises from the concept put forward by Newton that under conditions of parallel flow, the shearing stress is proportional to the velocity gradient. If the force acting on each of two planes of area A parallel to each other, moving parallel to each other with a relative velocity V, and separated by a perpendicular distance X, be denoted by F, the shearing stress is F/A and the velocity gradient, which will be linear for a true liquid, is V/X. Thus, $F/A = \eta\ V/X$, where the constant η is the viscosity coefficient or dynamic viscosity of the liquid. The poise is the CGS unit of dynamic viscosity.
POUNDAL (pdl). *A unit of force. One poundal equals the force required to give a standard 1-pound body an acceleration of 1 foot per second per second.*
QUART (qt). Because the gallon, quart, and pint differ in the United States and the United Kingdom, the use of this unit and term is generally discouraged for scientific purposes. One U.S. quart equals: (1) 946.4 cubic centimeters; (2) 0.03342 cubic foot; (3) 57.75 cubic inches; (4) 9.464×10^{-4} cubic meter; (5) 1.238×10^{-3} cubic yard; (6) 0.25 U.S. gallon; or (7) 0.9463 liter.
RAD (rd). *A unit of absorbed dose in the field of radiation dosimetry. One rad equals the absorption of energy in any medium of 100 ergs per gram.*
RADIAN (rad). *A unit of plane angle. One radian equals the angle subtended at the center by a circular arc which is equal in length to the radius of the circle.* (The SI unit of plane angle.)
REM (rem). *A unit of dose equivalent in the field of radiation dosimetry. One rem equals the amount of ionizing radiation of any type which produces the same damage to humans as 1 roentgen of approximately 200 kilovolts x-radiation.* (The unit is abbreviation of Roentgen Equivalent Man.)
REVOLUTION PER MINUTE (r/min). Although use of rpm as an abbreviation is common, it should not be used as a symbol.

TABLE 3. (*continued*)

ROENTGEN (R). A unit of exposure in the field of radiation dosimetry. That quantity of x–or gamma-radiation such that the associated corpuscular emission per 0.001293 gram of dry air (equals 1 cubic centimeter at 0°C and 769 millimeters of mercury pressure) produces in air ions carrying 1 esu of quantity of electricity of either sign. (The emu (electrostatic unit) is a unit in the CGS system in which the statcoulomb is the charge that repels an exactly similar charge in a vacuum with a force of 1 dyne. One statcoulomb equals 3.3356×10^{-10} coulomb.)

SECOND (s). *A unit of time. The duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the* ^{133}*Cs (cesium) atom.* (The SI unit of time.)

SLUG (slug). *A unit of mass. One slug equals 14.5959 kilograms.*

STERADIAN (sr). *A unit of solid angle. One steradian equals the solid angle subtended at the center by* $\frac{1}{4}\pi$ *of the surface area of a sphere of unit radius.*

STILB (sb). *A unit of luminance. One stilb equals 1 candela per square centimeter.*

STOKES (St). A unit of kinematic viscosity. The centistokes (cSt) is more commonly used. Kinematic viscosity is the dynamic viscosity divided by the density. See POISE given previously in this list.

TESLA (T). *A unit of magnetic flux density (magnetic induction). The magnetic flux density of a uniform field that produces a torque of 1 newton-meter on a plane current loop carrying 1 ampere and having a projected area of 1 square meter on the plane perpendicular to the field.* $T = N/A \cdot m$. (The SI unit of magnetic flux density.)

THERM (thm). *A unit of heat. One therm equals 100,000 British thermal units.*

TON (ton). A unit of weight. If not otherwise specified, a *short ton* equal to 2,000 pounds is assumed. A *long ton* equals 2,240 pounds. A metric ton equals 1,000 kilograms (2,205 pounds), also called *tonne* (t).

VAR (var). *A unit of reactive power. The reactive power at the port of entry of a single-phase two-wire circuit when the product of (a) the rms (root mean square) value in amperes of the sinusoidal current, (b) the rms value in volts of the voltage, and (c) the sine of the angular phase difference by which the voltage leads the current is equal to 1.* (The SI unit of reactive power.)

VOLT (V). *A unit of voltage. The voltage between 2 points of a conducting wire carrying a constant current of 1 ampere, when the power dissipated between these points is 1 watt.* (The SI unit of voltage.)

VOLTAMPERE (VA). *A unit of apparent power. The apparent power at the port of entry of a single-phase two-wire circuit when the product of (a) the rms (root mean square) value in amperes of the current and (b) the rms value in volts of the voltage is equal to 1.* (The SI unit of apparent power.)

WATT (W). *A unit of power. The watt equals 1 joule per second.* (The SI unit of power. One watt equals: (1) 3.4192 Btu/hour; (2) 0.05688 Btu/minute; (3) 10^7 ergs/second; (4) 44.27 foot-pounds/minute; (5) 0.7378 foot-pounds/second; (6) 1.341×10^{-3} horsepower; (7) 1.360×10^{-3} metric horsepower; (8) 0.01433 kilogram-calories/minute; or (9) 0.001 kilowatt.

WATT PER METER KELVIN ($W/m \cdot K$). The SI unit of thermal conductivity.

WATT PER STERADIAN (W/sr). The SI unit of radiant intensity.

WATT PER STERADIAN SQUARE METER ($W/Sr \cdot m^2$). The SI unit of radiance.

WATTHOUR (Wh). *A unit of energy. One watthour equals 3,600 joules.* (One watthour equals: (1) 3.413 Btu; (2) 3.60×10^{10} ergs; (3) 2,656 footpounds; (4) 859.85 gram-calories; (5) 1.341×10^{-3} horsepower-hour; (6) 0.8598 kilogram-calorie; (7) 367.2 kilogram-meters; or (8) 0.001 kilowatt-hour.

WEBER (Wb). *A unit of magnetic flux. The magnetic flux passing through an area of 1 square meter placed normal to a uniform magnetic field of magnetic flux density equal to 1 tesla.* $Wb = T \cdot m^2$. (The SI unit of magnetic flux.) If the flux linked by a circuit changes at a uniform rate of 1 weber per second, a voltage of 1 volt is induced in the circuit. $Wb = V \cdot s$.

*Although, officially, A (without small circle over it) may be used as an abbreviation or symbol for angstrom, to avoid possible confusion with the use of A for ampere, the Å symbol is used throughout this text.

A number of derived units have been given special names and symbols. See Table 1.

Decimal multiples of the coherent base and derived SI units are formed by attaching to these units the prefixes shown in Table 2.

The following units were accepted by the International Committee of Weights and Measures for use with the SI units for a transitional period: angstrom ($1 Å = 10^{-10}$ m), barn ($1b = 10^{-28}$ m^2), bar ($1bar = 10^5$ Pa), standard atmosphere (1 atm = 101,325 Pa), curie ($1Ci = 3.7 \times 10^{10}$ s^{-1}), roentgen ($1R = 2.58 \times 10^{-4}$ C/kg), rad (1 rad = 10^2 J/kg).

The *cgs system of units*, based on the centimeter, gram, and second as units in mechanics, is a metric system which continues to be used in some branches of physics. In daily life, the customary units in the United States are those based on the foot, pound-force, and second, but these units are

TABLE 4. COMMON EQUIVALENTS AND CONVERSIONS

Approximate common equivalents		Conversions accurate to parts per million	
1 inch	25 millimeters	inches × 25.4*	millimeters
1 foot	0.3 meter	feet × 0.3048*	meters
1 yard	0.9 meter	yards × 0.9144*	meters
1 mile	1.6 kilometers	miles × 1.60934	Kilometers
1 square inch	6.5 square centimeters	square inches × 6.4516*	Square centimeters
1 square foot	0.09 square meter	square feet × 0.0929030	square meters
1 square yard	0.8 square meter	square yards × 0.836127	square meters
1 acre	0.4 hectare	acres × 0.404686	hectares
1 cubic inch	16 cubic centimeters	cubic inches × 16.3871	cubic centimeters
1 cubic foot	0.03 cubic meter	cubic feet × 0.0283168	cubic meters
1 cubic yard	0.8 cubic meter	cubic yards × 0.764555	cubic meters
1 quart (liquid)	0.9463 liter	quarts (liquid) × 0.946353	liters
1 gallon	0.004 cubic meter	gallons × 0.00378541	cubic meters
1 ounce (avoirdupois)	28 grams	ounces (avoirdupois) × 28.3495	grams
1 pound (avoirdupois)	0.45 kilogram	pounds (avoirdupois) × 0.453592	kilograms
1 horsepower	0.75 kilowatt	horsepower × 0.745700	kilowatts
1 millimeter	0.04 inch	millimeters × 0.0393701	inches
1 meter	3.3 feet	meters × 3.28084	feet
1 meter	1.1 yards	meters × 1.09361	yards
1 kilometer	0.6 mile	kilometers × 0.621371	miles
1 square centimeter	0.16 square inch	square centimeters × 0.155000	square inches
1 square meter	11 square feet	square meters × 10.7639	square feet
1 square meter	1.2 square yards	square meters × 1.19599	square yards
1 hectare	2.5 acres	hectares × 2.47105	acres
1 cubic centimeter	0.06 cubic inch	cubic centimeters × 0.0610237	cubic inches
1 cubic meter	35 cubic feet	cubic meters × 35.3147	cubic feet
1 gram	0.035 ounce (avoirdupois)	grams × 0.0352740	ounces (avoirdupois)
1 kilogram	2.2 pounds (avoirdupois)	kilograms × 2.20462	pounds (avoirdupois)
1 kilowatt	1.3 horsepower	kilowatts × 1.34102	horsepower

rarely used in physics except for the description of equipment (e.g., "a 2-inch pipe"). Considerable effort has been going forth in the United States and a number of other countries that are not accustomed to using the metric system to ultimately adopt it.

About one hundred of the most frequently used units are defined in Table 3. Common equivalents and conversions are given in Table 4.

UPSILON PARTICLE. As of 1977, when the upsilon particle was discovered at the Fermi National Accelerator Laboratory, the particle was the heaviest to be identified. Discovery of upsilon prompted physicists to introduce a massive new quark, raising the number of quarks from four to five (but probably six). The upsilon has a mass three times greater than any subatomic entity previously detected. It was discovered in energetic collisions between protons and copper nuclei. With a mass at its lower energy state equivalent to 9.0 GeV and masses in excited states equivalent to 10 and 10.4 GeV, the upsilon particle has been interpreted

by scientists as consisting of a massive new quark (fifth) bound to its antiquark. The experiment was later reinforced by research at the Deutsches Elektronen-Synchrotron (DESY), located near Hamburg. At Fermilab, the excited upsilon particle appeared as a resonance in the yield of muons generated in collisions between protons and nuclei. A discussion of the upsilon experiment is described by a principal scientist of the project, L.M. Lederman (*Sci. Amer.*, **239**(4), 72–80, 1978). See also **Particles (Subatomic)**.

URALITE. A metamorphic mineral. It is well established that pyroxene rocks may be metamorphosed into hornblende rocks. If the hornblende thus produced is fibrous and retains the original form of the pyroxene, it is called uralite, and the process by which the change is brought about chemical process which in many cases is accompanied by the generation chemical process which in many cases is accompanied by the generation of new minerals such as calcite, epidote, and magnetite. Uralite was first observed in rocks from the Ural Mountains, hence its name. See also **Hornblende**.

URANINITE. A mineral approximating the composition UO_2, but containing besides the higher oxide of uranium, UO_3, and oxides of lead, thorium, and rare earths. The uraninite usually occurs as cubic or cubo-octahedral crystals of specific gravity 7.5–10; when in masses of pitchy luster it is called pitchblende, specific gravity 6.5–9. All uraninites and pitchblende contain a minute amount of radium. It was in pitchblende obtained from the Joachimsthal in Czechoslovakia that Mme Curie discovered radium. Other localities for uraninite are in Saxony, Rumania, Norway, Cornwall, East Africa, and in the United States in the pegmatites of Connecticut Grafton Center, New Hampshire, North Carolina, and South Dakota, and in Gilpin County, Colorado. An important occurrence of pitchblende is at Great Bear Lake, Northwest Territories, Canada, where it has been found in large quantities associated with silver.

URANIUM. [CAS: 7440-61-1]. Chemical element symbol, U, at. no. 92, at. wt. 238.03, periodic table group (Actinides), mp 1,131 to 1.133°C, bp 3,818°C, density 18.9 g/cm^3 (20°C). Uranium metal is found in three allotropic forms: (1) *alpha phase*, stable below 668°C, orthorhombic; (2) *beta phase*, existing between 668 and 774°C, tetragonal; and (3) *gamma phase*, above 774°C, body-centered cubic crystal structure. The gamma phase behaves most nearly that of a true metal. The alpha phase has several nonmetallic features in its crystallography. The beta phase is brittle. See also **Chemical Elements**.

Prior to the production of artificially-created elements, uranium was the highest in terms of atomic number and atomic weight. It was difficult to locate uranium in the periodic table of the elements, although chemically uranium resembles the elements of group 6b, namely, chromium, molybdenum, and tungsten. Subsequent to the production of the transuranium elements (atomic numbers 93 through 103), these elements, along with actinium (89), thorium (90), protactinium (91), and uranium (92) have been placed into the Actinide group of transition elements. They are similar in their mutual relations to the rare-earth group lanthanum (57) to lutetium (71). See also **Periodic Table of the Elements**.

Earthly abundance of uranium will be described shortly. In terms of presence in seawater, no significant concentrations have been reported. In terms of cosmic abundance, uranium also is very scarce. The study by Harold C. Urey (1952), in which silicon was given a base figure of 10,000, the concentration of uranium was represented by a figure of 0.0002.

Uranium is a white metal, ductile, malleable, and capable of taking a high polish, but tarnishes readily on exposure to the atmosphere. Finely divided uranium burns upon exposure to air, and the compact metal burns when heated in air at 170°C. Uranium metal slowly decomposes water at ordinary temperatures and rapidly at 100°C; is soluble in HCl and in HNO_3; and is unattacked by alkalis. Chemically related to chromium, molybdenum, and tungsten; and, like thorium, is radioactive. In the radioactive decomposition radium is formed. Discovered by Klaproth in 1789.

The element uranium found in nature consists of the three isotopes of mass numbers 238, 235, 234 with relative abundances 99.28, 0.71, and 0.006%, respectively.

The isotope ^{238}U is the parent of the natural uranium $4n + 2$ radioactive series, and the isotope ^{235}U is the parent of the natural actinium $4n + 3$ radioactive series.

The isotope ^{235}U has great importance because it undergoes the nuclear fission reaction with slow neutrons, and it has been separated in substantial amounts in nearly 100% isotopic composition.

Electronic configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^3 6s^2 6p^6 6d^1 7s^2$. Ionic radii U^{4+} 0.89 Å; U^{3+} 1.04 Å (Zachariasen). Metallic radius 1.4318 Å (805°C). Oxidation potential $U + 2H_2O \longrightarrow UO_2{}^{2+} + 4H^+ + 6e^-$, 0.82 V.

Uranium (^{233}U) is a fissionable isotope of uranium produced artificially by bombarding thorium-232 with neutrons. Used as an atomic fuel in molten salt reactor and is a possible fuel in breeder reactors. Half-life 1.62×10^5 years.

Uranium Reserves

Uranium has been known to be a distinct element since 1789. Apart from the small amount of its salts used in yellow pottery glazes, however, it remained more or less a laboratory curiosity until the 1920s. Then, the treatment of uranium ore, for the recovery of its radium (for the treatment of cancer), began in Eastern Europe and Zaire, followed by Canada in 1933. The separated uranium was mostly stockpiled or discarded.

After the development and successful explosion of the atomic bomb toward the end of World War II, an urgent search for workable uranium deposits was set in motion all over the world. The only high-grade deposits known to the western world were those in the countries just named as radium sources, but in view of the limited demand previously, serious exploration for uranium had never been undertaken. However, the offer of contracts by the U.S. Atomic Energy Commission, for fixed quantities at stated prices stimulated exploration for this hitherto largely ignored material.

Uranium is rather widely distributed throughout the world. See Table 1. Deposits vary markedly in richness.

Uranium Reserves

During the past few decades, the construction of new nuclear power reactors in the United States has been limited, although this does not hold for France and some other countries. As with any nonrenewable

TABLE 1. TYPES OF NATURAL URANIUM RESOURCES

Type of resource	Ore grade (ppm uranium)	Principal known locations
Vein deposits	10,000–30,000	Canada (near Great Bear Lake in the Northwest Territory) Western United States France Germany Russia Africa Australia China
Vein deposits (pegmatites, unconformity deposits)	2,000–10,000	Canada (Saskatchewan) Russia. Australia
Fossil placers, sandstones	200–2,000	Canada (Ontario) Western United States Brazil Chile Russia Japan Australia Africa
Shales, phosphates	10–100	United States (Florida) Morocco Sweden Russia
Pegmatites, other igneous and metamorphic	1–10	Canada (Ontario) deposits Greenland Brazil Spain Russia India Africa Australia

fuel, there is concern over some ultimate date in the future when the supply may approach exhaustion. As of the early 1990s, with a new period of calm prevailing pertaining to the need for construction of nuclear weaponry, forecasts of useable uranium reserves made in earlier years no longer hold, and revised forecasts are lacking. In terms of current usage of uranium, there are several avenues available for conserving the fuel.

(1) *Improvement of uranium efficiency in thermal reactors* which consume more fissionable material than they breed. If it is assumed that on average a typical light-water reactor (LWR) is operated at 75% total capacity (load factor = 0.75), it will consume about 6000 tons of U_3O_8 per gigawatt of electrical output GWe over an expected 30-year reactor life. During this period, the reactor will produce about 5 tons of fissile plutonium, which is discharged in the spent fuel. In the past, minimal consumption of uranium has not been a major design goal. Improvements in reactors (not requiring major alterations) could effect savings of from 10 to 15% in uranium consumption even without considering fuel recycling. For example, simply enriching the level of U-235 from 3 to 4.2% would allow the fuel to remain in the reactor for 5 years instead of the usual 3 years. As pointed out by Hafenmeister (California Polytechnic University), the longer residence time and the higher enrichment would allow a greater fraction of the U-235 to be used, increasing the *in situ*generation and burning of plutonium, while at the same time reducing the discharge of plutonium by 30% (from 5 to 3.5 tons over lifetime of the reactor). If the burn-up of fuel is increased from the traditional 30,000 to 50,000 megawatt-days per ton, the level of U-235 in the discharged fuel is reduced from 0.85% to 0.71%, and refueling can be considered either on a 12- or an 18-month cycle.

(2) *Design changes in new reactors can conserve uranium.* Traditional LWRs use control poisons such as boric acid in the reactor coolant as a means to reduce reactivity. This practice results in a waste of from 5 to 10% of available neutrons. Newer designs which would allow faster and more frequent refueling could reduce the need for such poisons and consequent loss of neutrons. Such changes could result in a saving of some 25% of the fuel required.

(3) *Reprocessing of spent fuel and blanket materials*, with the recovery of purified uranium and plutonium, could effect another fuel savings of nearly 20%. Such reprocessing not only would conserve the U_3O_8 supply, but would also alleviate a severe nuclear waste problem. As described in the entry on **Nuclear Power Technology**, the spent-fuel storage facilities at existing nuclear power facilities already have reached or are rapidly approaching their full capacity, and new storage systems must be developed. Processes for spent-fuel recovery are described in the next section of this article. The principal deterrent to reprocessing is concern with "nuclear proliferation." In the most straightforward reprocessing scheme, plutonium is recovered along with uranium. Plutonium is the primary ingredient of nuclear weapons. Contemporary nuclear power plants operating in a number of countries do not yield plutonium in a form useful for weapons production, whereas a fuel reprocessing scheme would.

(4) *Extending uranium supplies by using thorium in LWRs.* Instead of using boron as a poison in the coolant, 40% heavy water (D_2O) could be used along with thorium. Hafemeister observes that the heavier D_2O in this "spectral shift control reactor" would result in breeding and then burning more plutonium from the fertile U-238. It is estimated that the savings would be about 12% of the U_3O_8 when compared to the LWR on a conventional uranium cycle; and about 20% of the U-233 required for a LWR on a thorium cycle. The Canada Deuterium Uranium (CANDU) power reactors are described under "Heavy Water Reactor" in the entry on **Nuclear Power Technology**. This means of uranium conservation, of course, would require large capital expenditures.

(5) *Fast breeder reactors.* These reactors (FBRs) produce more fissionable material during operation than is originally furnished. A number of nations are interested in the FBR as a means of extending their available uranium. Plutonium is more valuable in an FBR because it raises breeding ratios by 10 to 20% when compared with U-235. But, as pointed out in the entry on **Nuclear Power Technology**, the FBR essentially remains in the design and development stage. In terms of nuclear proliferation, uranium has an advantage over plutonium because isotopic enrichment is necessary to obtain weapons-usable material from a fuel containing both U-233 and U-238, whereas only chemical separations are required to purify plutonium from a fuel containing plutonium and uranium.

Uranium Spent-Fuel Reprocessing

In the PUREX process, the spent fuel and blanket materials are dissolved in nitric acid to form nitrates of plutonium and uranium. These are separated chemically from the other fission products, including the highly radioactive actinides, and then the two nitrates are separated into two streams of partially purified plutonium and uranium. Additional processing will yield whatever purity of the two elements is desired. The process yields purified plutonium, purified uranium, and high-level wastes. See also "Radioactive Wastes" in the entry on **Nuclear Power Technology**. Because of the yield of purified plutonium, the PUREX process is most undesirable from a nuclear weapons proliferation standpoint.

In a modified PUREX process (sometimes called coprocessing), the plutonium and uranium are not handled separately as their nitrates, but rather they are processed together, yielding plutonium diluted with uranium. The diluted product is useful for nuclear reactors, but not directly usable for nuclear weapons.

In the CIVEX fuel reprocessing system, most of the uranium is separated and purified from the spent nuclear reactor fuel, while some of the fission fragments, some of the uranium, and all of the plutonium are handled together. The system thus yields a fuel containing some of all three materials. The fission products render the fuel unsafe for any but sophisticated handling for a period of at least one year. The plutonium does not exist in high concentrations. Hafemeister (1979) observes that the costs of remote fabrication for CIVEX make it potentially attractive only for nations with large breeder reactor programs. In addition, the fission products in CIVEX fuels would, to some extent, act as poisons in thermal reactors, reducing the flow of neutrons.

Processing of Uranium Ores

Preconcentration of uranium ores by methods based on gravity, magnetic, or electrical properties, or by flotation have not been generally successful because of the softness of the raw materials and the absence of differing physical properties among the constituents. Thus, treatment has involved the whole ore wherein an extractant has been used. The uranium is recovered from solution after appropriate solid-liquid separations. Either an acid or alkaline extractant can be used. The extraction is enhanced by use of fine grinding of the ore, by increasing the concentration of extractant, and by using higher temperatures and oxidizing agents. The uranium can be separated from the inert material by solid-liquid separation, filtration, or countercurrent washing. The uranium is recovered from solution by treatment with ion-exchange resin or solvent extraction. Alkaline leaching predominates over the acid process. The process is illustrated and briefly described in the Fig. 1. The uranium concentrate produced requires additional refining before fabrication into a fuel for nuclear reactors. Generally, this is accomplished by dissolving the product in HNO_3, filtering, and treating the uranyl nitrate solution by solvent extraction methods.

Chemistry of Uranium

Uranium has the four oxidation states, (III), (IV), (V), and (VI); the ions in aqueous solution are usually represented as U^{3+}, U^{4+}, $UO_2{}^+$, and $UO_2{}^{2+}$. The oxidation-reduction scheme, on the hydrogen scale (in which the potential for $\frac{1}{2}H_2 \longrightarrow H^+$ is taken as zero) is indicated in Fig. 2.

The $UO_2{}^+$ ion is unstable in solution and undergoes disproportionation to U^{4+} and $UO_2{}^{2+}$. A few solid compounds of this oxidation state are known, as for example, UF_5 and UCl_5.

The ion U^{3+} forms intense red solutions in H_2O and is oxidized by water at an appreciable rate. The rate of oxidation appears to increase with increasing ionic strength, although concentrated solutions are said to be stabilized by strong acids such as hydrochloric. Solutions of uranium(IV) are green, and uranium(VI) solutions, yellow.

The (IV) and (VI) are the important oxidation states and therefore the more important phases of the chemistry of uranium may be related to the two oxides UO_2 and UO_3, uranium dioxide and uranium trioxide. A series of salts such as the chloride and sulfate, UCl_4 and $U(SO_4)_2 \cdot 9H_2O$ is

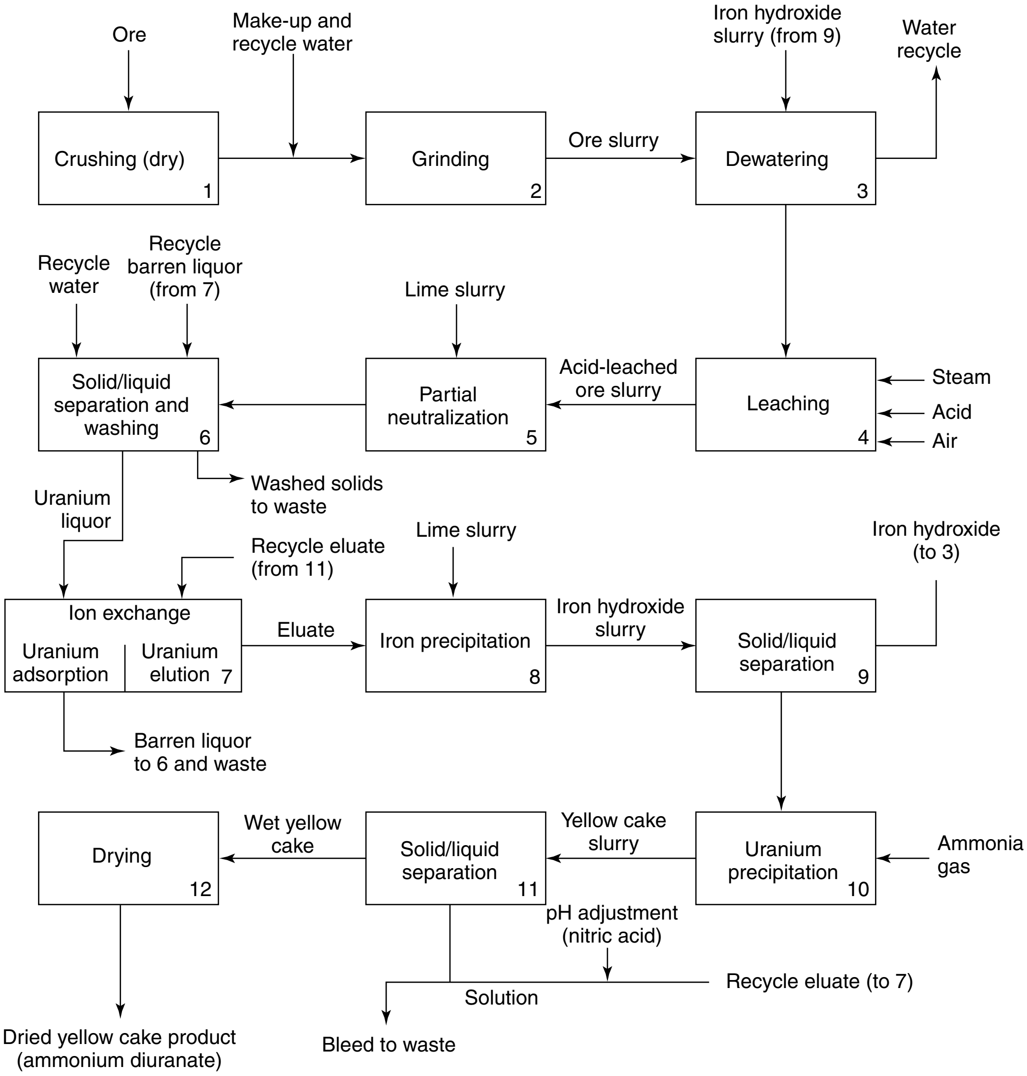

Fig. 1. Schematic flowsheet of uranium processing (acid leach and ion exchange) operation. Numbers refer to the numbers that appear in the boxes on the flowsheet. Operations (3), (6), (9), and (11) may be done by thickening or filtration. Most often, thickeners are used, followed by filters. The pH of the leach slurry (4) is elevated to reduce its corrosive effect and to improve the ion-exchange operation on the uranium liquor subsequently separated. In the ion exchange operation (7), resin contained in closed columns is alternately loaded with uranium and then eluted. The resin adsorbs the complex anions, such as $UO_2(SO_4)_3{}^{4-}$, in which the uranium is present in the leach solution. Ammonium nitrate is used for elution, obtained by recycling the uranium filtrate liquor after pH adjustment. Iron adsorbed with the uranium is eluted with it. Iron separation operation (8) is needed inasmuch as the iron hydroxide slurry is heavily contaminated with calcium sulfate and coprecipitated uranium salts. Therefore, the slurry is recycled to the watering stage (3). Washed solids from (6), the waste barren liquor from (7), and the uranium filtrate from (11) are combined. The pH is elevated to 7.5 by adding lime slurry before the mixture is pumped to the tailings disposal area. (*Rio Algom Mines Limited, Toronto*)

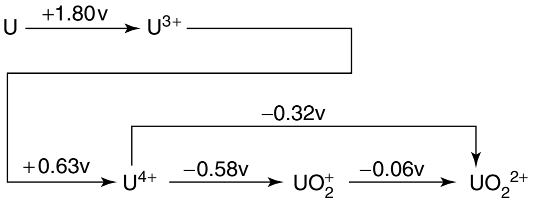

Fig. 2. Oxidation-reduction potentials of uranium ions (in 1-molar hydrochloric acid)

obtained from UO_2. The more common uranyl salts as $UO_2(NO_3)_2 \cdot 6H_2O$, UO_2Cl_2, and $UO_2SO \cdot nH_2O$ in which the $UO_2{}^{2+}$ (uranyl ion) acts as a radical, are derived from UO_3. UO_3 is amphiprotic and forms a series of alkali and double alkali uranates and polyuranates of limited solubility, such as $Na_2U_2O_7$, $NaZn(UO_2)_3(C_2H_3O_2)_9 \cdot 6H_2O$, $NaMg(UO)_2)_3(C_2H_3O_2)_9 \cdot 6H_2O$, etc.

The element uranium also exhibits a formal oxidation number of (II) in a few solid compounds, semimetallic in nature, such as UO and US. No simple uranium ions of oxidation state (II) are known in solution.

In addition to three oxides, UO_2 (brown, cubic), U_3O_8 (greenish black, orthorhombic) and UO_3 (orange, hexagonal), which have been known for a long time, there are known to exist the monoxide, UO, and the pentoxide U_2O_5. There is also some evidence for the existence of U_4O_7 and U_6O_{17}. The phase relationships in the uranium-oxygen system are very complex because solid solutions are readily formed, so that it is possible to obtain uranium "oxides" with practically any composition intermediate between UO and UO_3, and with many crystal structures.

Uranyl peroxide, the formula of which is usually given as $UO_4 \cdot 2H_2O$, is formed by precipitation from solutions of uranyl nitrate by hydrogen peroxide. Alkali hydroxides, hydrogen peroxide, and sodium peroxide form soluble peroxyuranates, $Na_2UO_6 \cdot 4H_2O$ and $Na_4UO_8 \cdot 8H_2O$, when added to solutions of uranyl salts.

Two uranium carbides are known, the monocarbide, UC, and the dicarbide, UC_2. These can be prepared by direct reaction of carbon with molten uranium, or by reaction of carbon monoxide with metallic uranium at elevated temperatures. The sesquicarbide, U_2C_3, has been found to exist as a stable compound below about 1800°C and can be produced by heating a mixture of UC and UC_2 between 1,250 and 1,800°C.

Uranium and nitrogen form an extensive series of compounds that can be prepared by direct action of nitrogen on the metal. Uranium mononitride,

UN, is the lowest nitride of uranium. If the mononitride is treated with more nitrogen at atmospheric pressure, U_2N_3 is formed. With nitrogen under high pressure UN_2 can be prepared, but it is difficult to obtain samples of UN_2 that are completely free of UN.

Uranium metal reacts with hydrogen at 250–300°C to form a well-defined hydride, which resembles the rare-earth hydrides in many respects. The formula of this substance has been shown to be $UH_{3.00}$. The hydride undergoes decomposition with increasing temperature; the dissociation pressure of UH_3 is one atmosphere at 436°C.

Uranium tetrafluoride serves as a starting material for the preparation of the other fluorides. It is best prepared by hydrofluorination of uranium dioxide:

$$UO_2 + 4HF \xrightarrow{500^\circ C} UF_4 + 2H_2O$$

Uranium trifluoride can be prepared by reduction of UF_4 with hydrogen at 1,000°C. Uranium hexafluoride, UF_6, white and orthorhombic, is best obtained by direct fluorination of UF_4, green and monoclinic, although any uranium compound will yield UF_6 by reaction with fluorine at elevated temperatures:

$$UF_4 + F_2 \xrightarrow{350^\circ C} UF_6$$

The hexafluoride can also be prepared by the interesting reaction:

$$2UF_4 + O_2 \xrightarrow{900^\circ C} UF_6 + UO_2F_2$$

The intermediate fluorides $U_2F_9(UF_{4.5})$, $U_4F_{17}(UF_{4.25})$ and UF_5 are prepared by reaction of solid UF_4 and gaseous UF_6 under appropriate conditions of temperature and pressure.

Uranium hexafluoride is probably the most interesting of the uranium fluorides. Under ordinary conditions, it is a dense, white solid with a vapor pressure of about 120 mm at room temperature. It can readily be sublimed or distilled, and it is by far the most volatile uranium compound known. Despite its high molecular weight, gaseous UF_6 is almost a perfect gas, and many of the properties of the vapor can be predicted from kinetic theory.

Uranium tetrachloride can be prepared by direct combination of chlorine with uranium metal or hydride; it can also be obtained by chlorination of uranium oxides with carbon tetrachloride, phosgene, sulfur chloride, or other powerful chlorinating agents. The trichloride is obtained by reaction of UCl_4 with hydrogen and the higher chlorides by reaction of UCl_4 and Cl_2. Uranium hexachloride, UCl_6 is a rather volatile, somewhat unstable substance. All of the uranium chlorides dissolve in or react readily with water to give solutions in which the oxidation state of the ion corresponds to that in the solid. All of the solid chlorides are sensitive to moisture and air.

The trichloride, tribromide and triiodide of uranium are obtained either by reaction of the elements or by treatment of UH_3 with the appropriate halogen acid. The thermal stability of the halides decreases as the atomic number of the halogen increases. No higher uranium bromides or iodides are known.

A series of oxyhalides of the type UO_2F_2, $UOCl_2$, UO_2Br_2, etc., are known. They are all water-soluble substances which become increasingly less stable in going from the oxyfluoride to the oxyiodide.

Uranyl ion forms complexes with many oxy anions. Both U(VI) and U(IV) compounds dissolve in alkali carbonate solutions with formation of carbonato complexes. Those of the larger alkali cations are only slightly soluble: $K_{sp} = 6 \times 10^{-5}$ for both $K_4[UO_2(CO_3)_3]$ and $(NH_4)_4[UO_2(CO_3)_3] \cdot 2H_2O$.

Aqueous solutions of uranium(III), uranium(IV), and uranium(VI) are readily obtained. Solutions of uranium(III) are blood-red in appearance; hydrogen is slowly evolved with the formation of uranium(IV) is a strong reducing agent and is easily oxidized to uranyl ion by oxygen, peroxide, and numerous other oxidizing agents. Uranyl solutions in turn may be reduced to uranium(IV) with sodium dithionite, zinc or cadmium amalgams, or by electrochemical or photochemical means.

Separation of Isotopes

Several methods are available for the separation of isotopes, including gaseous diffusion, centrifugation, electromagnetic methods, thermal diffusion, electrolytic methods, distillation, and chemical-exchange methods. In the late 1960s, another, radically different process was added to the technology of isotope separation. This is known as laser enrichment and is described shortly. The separation of ^{235}U from ^{238}U represented the first large-scale isotope-separation operation and, after considerable study, the principal plant utilized gaseous diffusion.

The gaseous diffusion method of isotope separation is based upon the difference in the rate of diffusion of gases that differ in density. Since the rate of diffusion of a gas is inversely proportionate to the square root of its density, the lighter of two gases will diffuse more rapidly than the heavier. Therefore, the result of a partial diffusion process will be an enrichment of the partial product in the lighter component.

To separate isotopes by this process, they must be in the gaseous form. Therefore, the separation of isotopes of uranium required the conversion of the metallic uranium into a gaseous compound, for which purpose the hexafluoride, UF_6, was chosen. Since the atomic weight of fluorine is 19, the molecular weight of the hexafluoride of ^{235}U is $235 + (6 \times 19) = 349$, and the molecular weight of the hexafluoride of ^{238}U is $238 + (6 \times 19) = 352$. Since the rate of diffusion of a gas is inversely proportional to the square root of its density (mass per unit volume), the maximum separation factor for one diffusion process of the uranium isotopes is $\sqrt{352/349} = 1.0043$. Since only part of the gas can be allowed to diffuse, the actual separation factor is even less than this theoretical maximum.

From this small figure, it is apparent that many diffusion stages are necessary in the separation of ^{235}U from ^{238}U. The number originally calculated for the Oak Ridge plant was about 4,000. Other reasons are the small apertures demanded by diffusion processes (in this case less than. 00001 centimeter in diameter), which reduce the rate of gas flow and demand a great barrier area for appreciable production.

The centrifugal method of isotope separation consists essentially of the passage of the mixture through a rapidly rotating force field, such as that of a rotating cylinder. If a current of mixed gases is passed into such a cylinder, moving parallel to the axis of rotation, the lighter gas will tend to concentrate near the axis, and the heavier gas, near the periphery. This is the principle of the cream separator; its successful application to separation of isotopes in the gaseous phase requires apparatus operating at very high speeds of rotation.

The electromagnetic method of isotope separation is based upon the principle of the mass spectrograph. As in that apparatus, a stream of charged particles is passed through a system of electric and magnetic fields. If the particles are ions of two or more isotopes of the same element, all bearing the same charge, the deflections produced by the fields will vary with the masses of the particles, and will thus provide a means for their separation. This method is especially effective for the separation of particles of a number of masses, and has been widely used for that purpose in research studies and in production-separation operations. The method is also used extensively in a number of research laboratories, particularly those of northern Europe, for the isotopic separation of individual radioactive nuclides that are to be used as sources in instruments, such as beta- and gamma-ray spectrometers, in which measurements are made of the characteristics of ionizing radiations.

The thermal diffusion method of isotope separation has broad application to liquid-phase as well as gaseous-phase separations. The apparatus widely used for this purpose consists of a vertical tube provided with an electrically heated central wire. The gaseous or liquid mixture containing the isotopes to be separated is placed in the tube, and heated by means of the wire. In such an apparatus two effects act to separate the isotopes. Thermal diffusion tends to concentrate the heavier isotopes in the cooler outer portions of the system, while the portions near the hot wire are enriched in the lighter isotopes. At the same time, thermal convection causes the hotter fluid near the hot wire to rise, while the cooler fluid in the outer portions of the system tends to fall. The overall result of these two effects causes the heavier isotopes to collect at the bottom of the tube and the lighter at the top, whereby both fractions may be withdrawn.

The electrolytic method of isotope separation is of importance not only because of its present day uses, but also because of its historical interest. It was by this method that G.N. Lewis and his co-workers at the University of California obtained practically pure deuterium. Since deuterium oxide had been shown to be present in ordinary water, the conclusion was drawn that water (or rather the dilute aqueous solution) from electrolytic cells used for the production of hydrogen and oxygen by continuous electrolysis of water, should be richer in the heavier isotope (deuterium having a mass number of 2, as against 1 for protium). Starting with such residual water from an electrolytic cell, it was found that by repeated electrolysis a small residue consisting almost entirely of deuterium oxide (D_2O) was obtained. This process is still used for the separation of pure hydrogen isotopes, as well as for other purposes.

The distillation method of isotope separation has also been the basis of important research contributions. In the work on the hydrogen isotopes, it preceded the electrolytic separation methods discussed above. Following the suggestion by Birge and Menzel, of the possible presence of deuterium in ordinary hydrogen to the extent of 1 part in about 4,500, Urey, Brickwedde and Murphy, in 1931, began their search for this isotope. By evaporating about 4,000 milliliters of liquid hydrogen to a volume of about 1 milliliter, Brickwedde obtained a residue that gave conclusive spectroscopic evidence of the presence of deuterium. The distillation method of separation has been responsible for many other research contributions. Among them may be mentioned separation of the isotopes of oxygen, of mercury, zinc, potassium and chlorine.

The chemical exchange methods of isotope separation are of value, not only for that purpose, but also because they provide a direct means for the study of chemical reactions. A well-known example of an isotopic chemical exchange is the heavy water equilibrium:

$$H_2 + D_2O \rightleftharpoons D_2 + H_2O$$

In this equation, the formula H_2 is used for the hydrogen isotope of mass number 1, which constitutes all but a small fraction of ordinary hydrogen; H_2O is the corresponding "light water"; D_2 is hydrogen of mass number 2 (deuterium) and D_2O is the corresponding heavy water. The double arrows indicate an equilibrium reaction, whereby under suitable conditions ordinary hydrogen reacts with heavy water to produce hydrogen of mass number 2 and light water. If one were to start either with the two reactants on the left of the arrows, or with the two on the right, the system at equilibrium would have all four present. However, in this system at equilibrium the reverse reaction predominates, so that the ratio of ^2H to ^1H (that is, the ratio of D_2O to H_2O) in the liquid phase is about three times as great as in the gas. Because of this differential reactivity, this method is useful in the separation of the two hydrogen isotopes.

Another equilibrium system is useful in the separation of ^{14}N and ^{15}N. It is represented by the equation:

$$^{15}NH_3 + {}^{14}NH_4NO_3 \rightleftharpoons {}^{14}NH_3 + {}^{15}NH_4NO_3$$

This exchange reaction is conducted by the countercurrent flow of ammonia gas and ammonium nitrate solution (in water). The forward reaction is favored, resulting in the concentration of the ^{15}N in the ammonium nitrate in solution. The multistate conduct of this reaction that is necessary for effective operation is accomplished by arranging later stages in which the enriched ammonium nitrate solution is divided into two parts. One part is treated with caustic soda to displace the enriched NH_3, which is then used in a second stage of the process with the other part of the NH_4NO_3 solution. Three or more stages may thus be used, until the desired concentration of ^{15}N has been effected.

Another method of isotope separation is by ion mobility, a process based on the difference in mobility of the ions in an electrolytic solution, under the influence of an electric field.

The laser process for enrichment of uranium dates back to the early 1970s. In addition to early and continuing development of this process at the Lawrence Livermore National Laboratory, pioneering efforts were made by Exxon Nuclear Corporation and Avco Corporation in early 1971. These efforts concentrated on an atomic vapor laser isotope separation approach. The process now in a reasonably late stage of development at the Lawrence laboratory is known by the acronum AVLIS (for atomic vapor laser isotope separation). The process differs radically from all other uranium enrichment approaches. The AVLIS processes uses a bank of very finely tuned lasers to create an electrical charge on uranium-235 atoms while leaving nonfissle uranium-238 atoms unchanged. Fundamentally, the process involves the firing of light from high-powered copper-vapor lasers into a stream of uranium atoms. Through tuning of the lasers, electrons will be stripped from some of the atoms, thus leaving positively charged uranium-235 ions. These are drawn to negatively charged plates. The uncharged uranium-238 atoms pass through the process unaffected. Advantages claimed for the process include a smaller capital investment to build and less costly to operate and maintain. Also, the construction of laser plants can be smaller and modular as compared with the former huge diffusion, centrifuge, and magnetic plants.

Health and Safety Factors

Exposure and Health Effects. Uranium is a general cellular poison, which can potentially affect any organ or tissue. Uranium and its compounds can be damaging due to chemical toxicity and by the injury caused by ionizing radiation. The chemical toxicity of uranium compounds depends on their solubility in biological media. Highly soluble and therefore highly transportable and toxic compounds include fluorides, chlorides, nitrates, and carbonates of uranium(VI); moderately transportable compounds include corresponding uranium(IV) compounds; slightly transportable compounds include oxides, hydrides, and carbides.

Uranium can enter the human body orally, by inhalation, and through the skin and mucous membranes. Uranium compounds, both soluble and insoluble, are absorbed most readily from the lungs. In the blood of exposed animals, uranium occurs in two forms in equilibrium with each other: as a nondiffusible complex with plasma proteins and as a diffusible bicarbonate complex.

Occupational Protection and Radiation Consideration. The main adverse factor during the mining and processing of uranium and uranium-containing minerals is airborne dust. Personal protection should be used. Finely divided uranium metal, some alloys, and uranium hydride are pyrophoric, therefore such materials should be handled in an inert atmosphere glovebox.

The toxicity of uranium caused by its radiation depends on the isotopes present. Natural uranium does not constitute an external radiation hazard since it emits mainly low energy α-radiation. It does, however present an internal radiation hazard if it enters the body by inhalation or ingestion. The concentration of 1 mg U/g biological tissue corresponds to an absorbed dose of 0.006 Sv per year. Large quantities of fissile isotopes, ^{233}U and ^{235}U, should be handled and stored appropriately to avoid a criticality hazard. Clear and relatively simple precautions, such as dividing quantities so that the minimum critical mass is avoided, following administrative controls, using neutron poisons, and avoiding critical configurations (or shapes), must be followed to prevent an extremely treacherous explosion.

UREA. [CAS: 57-13-6]. $H_2N \cdot CO \cdot NH_2$, formula weight 60.06, colorless crystalline solid, mp 132.7°C, sublimes unchanged under vacuum at its melting point, sp gr 1.335. Heating above the mp at atmospheric pressure causes decomposition, with the production of NH_3, isocyanic acid HNCO, cyanuric acid $(HNCO)_3$, biuret $NH_2CONHCONH_2$, and other products. Also known as carbamide, urea is very soluble in H_2O, soluble in alcohol, and slightly soluble in ether. The compound was discovered by Rouelle in 1773 as a constituent of urine. Historically, urea was the first organic compound to be synthesized from inorganic ingredients, accomplished by Wöhler in 1828. However, a century passed before the compound was manufactured on a large scale.

Because of the reactivity and versatility of its derivatives, urea is a very high-tonnage chemical. The compound and its derivatives are widely used in fertilizers, pharmaceuticals (e.g., barbiturates), and synthetic

resins and plastics (urethanes). Although there are several chemical engineering approaches to the synthesis of urea, the principal reaction is that of combining NH_3 with CO_2 in a first step to form ammonium carbamate. In a second step, dehydrating the ammonium carbamate to yield urea: (1) $2NH_3 + CO_2 \longrightarrow NH_2COONH_4$, (2) $NH_2COONH_4 \longrightarrow NH_2CONH_2 + H_2O$. The processing is complicated because of the severe corrosiveness of the reactants, usually requiring reaction vessels that are lined with lead, titanium, zirconium, silver, or stainless steel. The second step of the process requires a temperature of about 200°C to effect the dehydration of the ammonium carbamate. The processing pressure ranges from 160 to 250 atmospheres. Only about one-half of the ammonium carbamate is dehydrated in the first pass. Thus, the excess carbamate, after separation from the urea, must be recycled to the urea reactor or used for other products, such as the production of ammonium sulfate.

Some of the reactions of urea and derivatives include: (1) as a weak mono-acid base, urea forms stable salts, such as urea nitrate $CO(NH_2)_2 \cdot HNO_3$ and urea oxalate $2CO(NH_2)_2 \cdot H_2C_2O_4$; (2) urea reacts with malonic acid to form barbituric acid $CO(NHCO)_2CH_2$, the derivatives of which are barbiturates (sedative drugs); (3) with alcohols, urea reacts to form urethanes; (4) with formaldehyde, urea forms ureaforms which can be used as slow-release fertilizers and also as ingredients for adhesives and plastics; (5) with hydrogen peroxide, urea forms a useful crystalline oxidizing agent; (6) with straight-chain alkanes, urea forms crystalline complexes (clathrates) which are used in the petroleum industry for separating straight- and branched-chain hydrocarbons; (7) when heated rapidly to about 350°C in a fluidized bed at atmospheric pressure, urea decomposes to isocyanic acid and NH_3. The latter products, when passed over a catalyst at 400°C, yield melamine $(NCH_2)_3$ which is the triamide of cyanuric acid and widely used in plastics; (8) with acids or bases, urea hydrolyzes, yielding NH_3 and CO_2. Hydrolysis in aqueous solutions is accelerated by the presence of urease (an enzyme). This reaction frequently is used for the quantitative determination of urea; (9) upon heating aqueous solutions of urea, biuret is formed. When crystallizing urea from aqueous solutions, the presence of about 5% biuret alters the crystals from long needles to short rhombic prisms, the latter greatly enhancing the handling properties of the final product. A content of up to 1.5% biuret is satisfactory for most fertilizer applications, although for citrus fruits, coffee plants, and cherry trees, the biuret content must remain below 0.3%. As a feed supplement for ruminants, pure biuret has proved advantageous because of the slower release rate of NH_3 from biuret as compared with urea. See also **Fertilizer**.

There are several different processes for making urea fertilizer. One process designed for energy savings is shown in Figs. 1 and 2.

Arginine-Urea Cycle (Ornithine Cycle)

In adult animals, including humans, the characteristic tissue-specific levels of different enzymes are maintained by a dynamic balance between the independently controlled rates of biosynthesis and degradation of each enzyme. A dynamic rather than a static system most likely emerged because it enables organisms to adapt to widely different nutritional conditions and other environmental changes. Depending upon the physiological state of the animal at a given moment, amino acids derived from the hydrolysis of exogenous or endogenous protein may be predominantly utilized for *synthesis* of tissue-specific proteins. Or, their carbon chains may be *metabolized* further to provide energy (ATP) or intermediates for synthesis of other cellular constituents. When the carbon chains of amino acids are utilized to provide energy, some provision must be made for disposal of the reduced nitrogen components. Animal tissues in general cannot tolerate accumulation of ammonia. Aquatic animals, which are surrounded

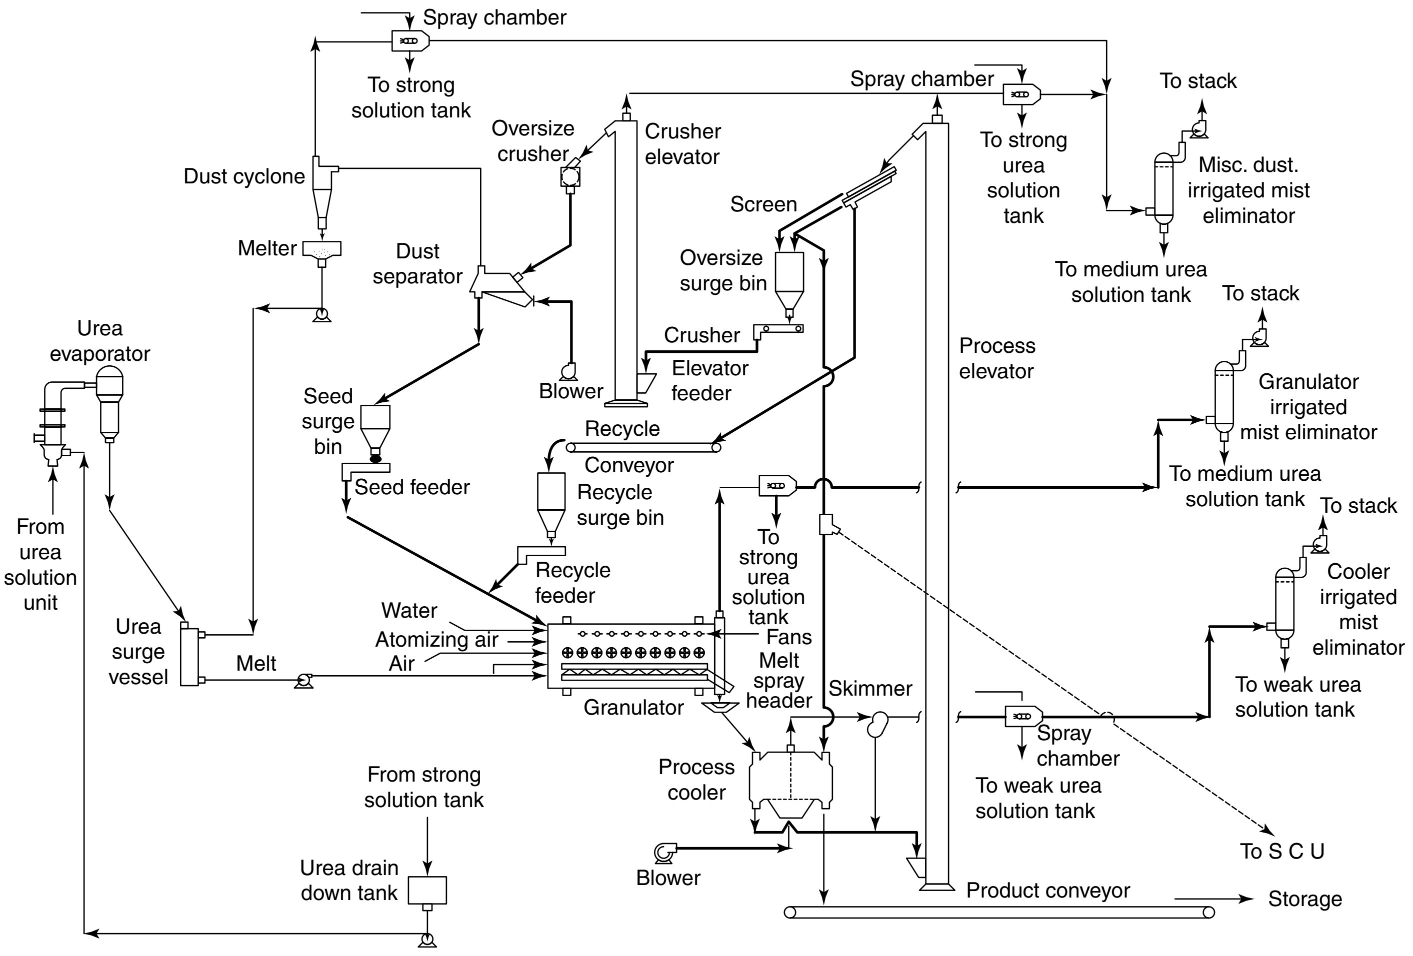

Fig. 1. A new process (*Urea Technologies*) developed for the Tennessee Valley Authority operates at considerable energy savings. Urea is produced in an overall exothermic reaction of ammonia and carbon dioxide at elevated pressure and temperature. In a highly exothermic reaction, ammonium carbamate is first formed as an intermediate compound, followed by its dehydration to urea and water, which is a slightly endothermic reaction. The conversion of CO_2 and NH_3 to urea depends on the ammonia-to-carbon dioxide ratio, temperature, and water-to-carbon dioxide ratio, among other factors. The new process makes maximum use of the heat created in the initial reaction, including heat recycling. (*Urea Technologies and Tennessee Valley Authority*)

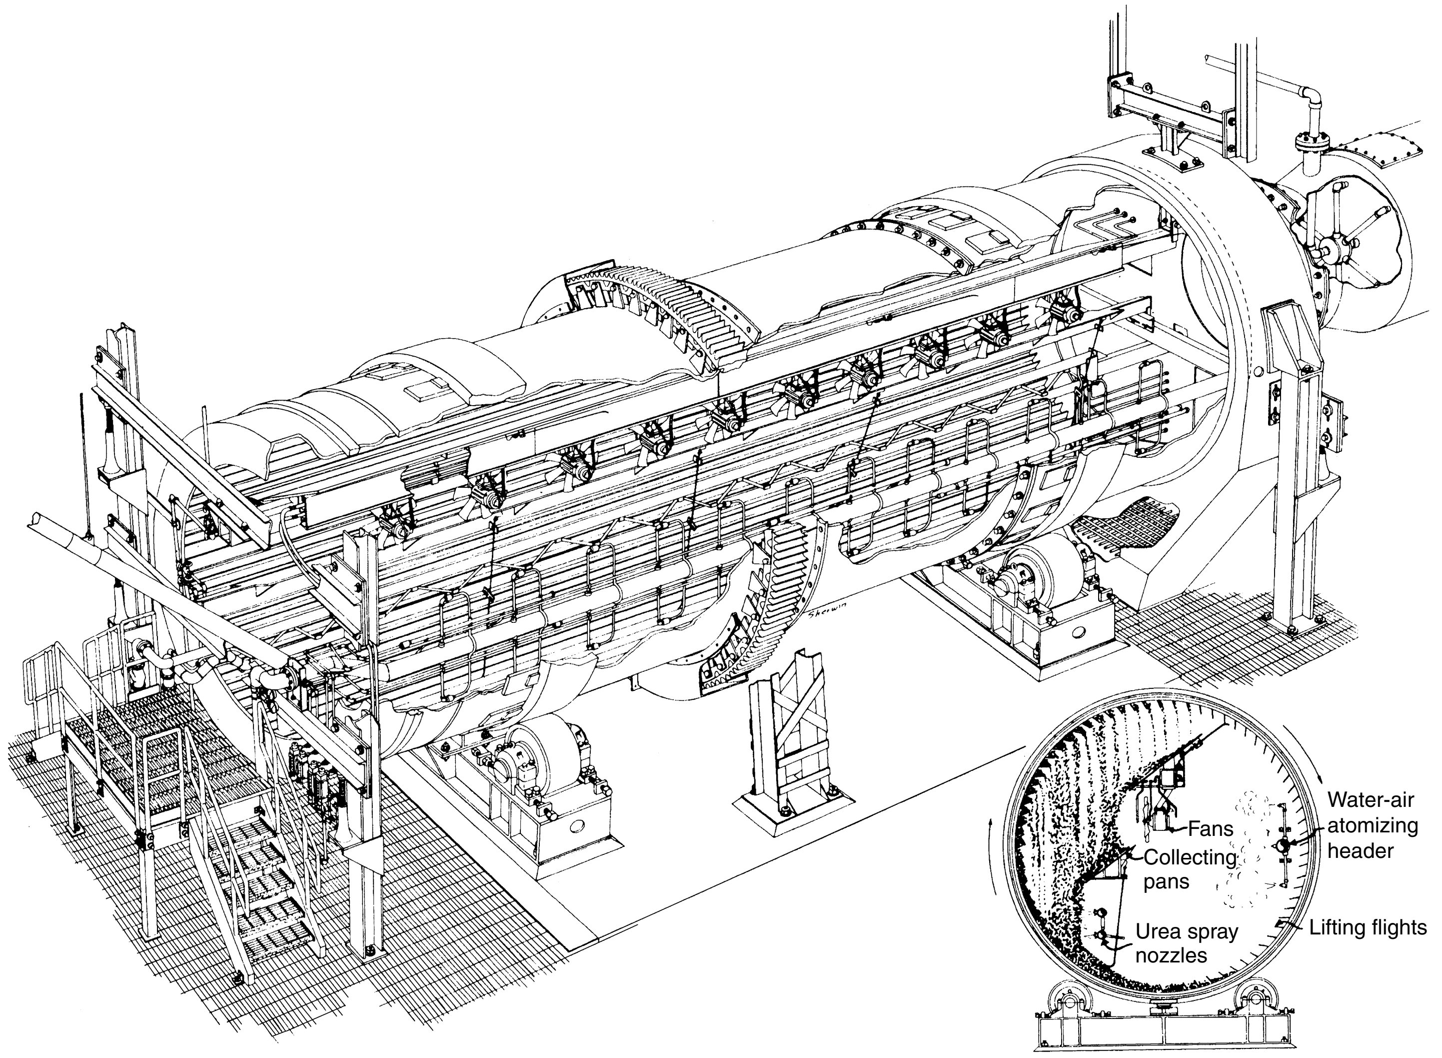

Fig. 2. In the urea process shown in Fig. 1, a falling-curtain granulation technique is used. The granulator drum is shown here. The key to the process is the rotary drum, with specially designed components, including collecting pans, air-circulation fans, urea spray header, and water spray header. As the drum rotates, seed particles, recycled undersize granules, and intermediate-size granules are lifted by flights and discharged onto inclined collecting pans. The material forms a dense falling curtain of granules as it slides from the collecting pans. The urea melt is sprayed through hydraulic atomizing nozzles onto this falling curtain and quickly solidifies. Controls over several variables in the process make it possible to form granules within narrow size specifications. Further details of process are given by Kirkland (*R.W. Kirkland, "Energy-efficient route to granular urea," Chemical Engineering Progress, April, 1984, pp. 49–53, April 1984*)

by a convenient diluent, can simply excrete ammonia as rapidly as it is formed. In contrast, land-based animals have devised other solutions to this problem. They convert amino acid nitrogen and ammonia into nitrogen-rich, nontoxic compounds, such as *urea* and *uric acid*. These are then excreted at intervals. Synthesis of urea, the primary nitrogenous excretory product of mammals, is efficiently accomplished in the liver by combining a portion of the already established pathway of arginine biosynthesis with the hydrolytic degradative enzyme, arginase.

Some of the enzymes required are widely distributed, but *ornithine carbamoyltransferase* occurs only in the liver and thus the complete urea cycle occurs only in that organ.

In human liver, a given molecule of arginine has four possible metabolic fates. It can be converted to (1) argininosuccinic acid, or (2) argininyl-sRNA, or (3) ornithine plus urea, or (4) ornithine plus glycocyamine, the precursor of creatine. The flow along the pathway to (4) is regulated by feedback repression in which the steady-state level of the enzyme involved (arginine:glycine amidinotransferase) is regulated by the concentration of liver creatine. Thus, runaway synthesis of creatine is prevented. The flow along the pathway is regulated by supply and demand.

Experimentally, it has been observed that above a certain basal level, the quantity of urea excreted is proportional to the amount of ingested protein.

The enzyme urease was not discovered until 1926 (by Sumner). It was the first enzyme to be isolated as a crystalline protein. Sumner's accomplishment confirmed the then growing belief that enzymes, the biological catalysts, were indeed from the chemical standpoint protein molecules. Urease catalyzes the cleavage of urea to ammonia and carbon dioxide.

For related information and references, see article on **Fertilizer**.

UREA-AMMONIUM ORTHOPHOSPHATE. A fertilizer developed especially for food-deficient regions, particularly rice-dependent areas. Several grades contain all three primary plant nutrients (nitrogen, phosphorus, and potassium). Contains up to 60% nitrogen, phosphoric anhydride and potassium oxide.

See also **Fertilizer**.

UREA-AMMONIUM POLYPHOSPHATE. A fertilizer similar to urea-ammonium othtrophosphate except that about half the phosphorus is in polyphosphate form, which gives improved sequestering action and solubility. It is excellent for use as a liquid fertilizer.

See also **Fertilizer**.

UREA AND THIOUREA DERIVATIVES. See **Herbicides**; **Insecticide**.

UREAFORM. A urea-formaldehyde reaction product that contains more than one molecule of urea per molecule of formaldehyde. It can be used as a fertilizer because of its high nitrogen content, its insolubility in water,

and its gradual decomposition in the soil during the growing season to yield soluble nitrogen.

UREA-FORMALDEHYDE RESIN. An important class of amino resin. Urea and formaldehyde are united in a two-stage process in the presence of pyridine, ammonia, or certain alcohols with heat and control of pH to form intermediates (methylolurea, dimenthylolurea) that are mixed with fillers to produce molding powders. These are converted to thermosetting resins by further controlled heating and pressure in the presence of catalysts. These were first plastics that could be made in white, pastel, and colored products.

See also **Amino Acids**; **Melamine**.

UREASE. Enzyme present in low-percentages in jackbean and soybean; water soluble, its action is inhibited by heavy-metal ions. Its principal use is in the determination of urea in urine, blood, and other body fluids; it splits urea into ammonia and carbon dioxide or ammonium carbonate.

See also **Urea**.

URECH CYANOHYDRIN METHOD. Cyanohydrin formation by addition of alkali cyanide to the carbonyl group in the presence of acetic acid (Urech); or by reaction of the carbonyl compound with anhydrous hydrogen cyanide in the presence of basic catalyst (Ultee).

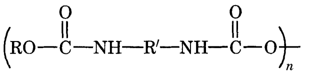
URECH HYDANTOIN SYNTHESIS. Formation of hydantoins from α-amino acids by treatment with potassium cyanate in a aqueous solution and heating of the salt of the intermediate hydantoic acid with 25% hydrochloric acid.

URETHANE. [CAS: 51-79-6]. $CO(NH_2)OC_2H_5$, also referred to as ethyl carbamate or ethyl urethane. Its structure is typical of the repeating unit in polyurethane resins. Colorless crystals or white powder, odorless, saltpeter-like taste, D 0.9862, mp 49C, bp 180C; solutions neutral to litmus, soluble in water, alcohol, ether, glycerol, and chloroform; slightly soluble in olive oil. Formed by the heating of ethanol and urea nitrate to 120–130°C or by the action of ammonia on ehtyl carbonate or ethyl chloroformate.

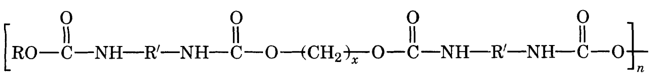
See also **Polyurethanes**.

URETHANE POLYMERS. The rapid formation of high molecular weight urethane polymers from liquid monomers, which occurs even at ambient temperature, is a unique feature of the polyaddition process, yielding products that range from cross-linked networks to linear fibers and elastomers. The enormous versatility of the polyaddition process allowed the manufacture of a myriad of products for a wide variety of applications.

Polyurethanes contain carbamate groups, −NHCOO−, also referred to as urethane groups, in their backbone structure. They are formed in the reaction of a diisocyanate with a macroglycol, a so-called polyol, or with a combination of a macroglycol and a short-chain diol extender. In the latter case, segmented block copolymers are generally produced. The macroglycols are based on polyethers, polyesters, or a combination of both. A linear polyurethane polymer has the structure of (**1**), whereas a linear segmented copolymer obtained from a diisocyanate, a macroglycol, and a diol extender, $HO(CH_2)_xOH$, has the structure of (**2**).

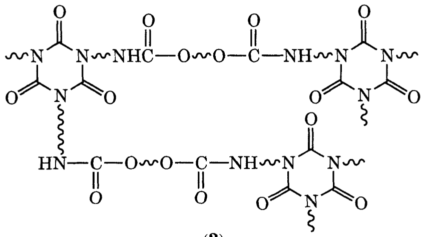


(**1**)



(**2**)

In addition to the linear thermoplastic polyurethanes obtained from difunctional monomers, branched or cross-linked thermoset polymers are made with higher functional monomers. Linear polymers have good impact strength, good physical properties, and excellent processibility, but, owing to their thermoplasticity, limited thermal stability. Thermoset polymers, on the other hand, have higher thermal stability but sometimes lower impact strength (rigid foams). The higher functionality is obtained with higher functional isocyanates (polymeric isocyanates), or with higher functional polyols. Cross-linking is also achieved by secondary reactions. Urea-modified segmented polyurethanes are manufactured from diisocyanates, macroglycols, and diamine extenders. Urethane network polymers are also formed by trimerization of part of the isocyanate groups. This approach is used in the formation of rigid polyurethane-modified isocyanurate (PUIR) foams (**3**).



(**3**)

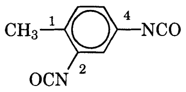
Formation and Properties

Polyurethane Formation. The polarization of the isocyanate group enhances the addition across the carbon-nitrogen double bond, which allows rapid formation of addition polymers from diisocyanates and macroglycols.

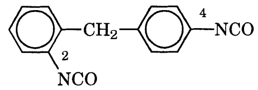
The liquid monomers are suitable for bulk polymerization processes. The reaction can be conducted in a mold (casting, reaction injection molding), continuously on a conveyor (block and panel foam production), or in an extruder (thermoplastic polyurethane elastomers and engineering thermoplastics). Also, spraying of the monomers onto the surface of suitable substrates provides insulation barriers or cross-linked coatings.

The polyaddition reaction is influenced by the structure and functionality of the monomers, including the location of substituents in proximity to the reactive isocyanate group (steric hindrance) and the nature of the hydroxyl group (primary or secondary). Impurities also influence the reactivity of the system.

The steric effects in isocyanates are best demonstrated by the formation of flexible foams from TDI. In the 2,4-isomer (**4**), the initial reaction occurs at the nonhindered isocyanate group in the 4-position. The unsymmetrically substituted ureas formed in the subsequent reaction with water are more soluble in the developing polymer matrix. Low density flexible foams are not readily produced from MDI or PMDI; enrichment of PMDI with the 2, 4′-isomer of MDI (**5**) affords a steric environment similar to the one in TDI, which allows the production of low density flexible foams that have good physical properties. The use of high performance polyols based on a copolymer polyol allows production of high resiliency (HR) slabstock foam from either TDI or MDI.



(**4**)



(**5**)

Tailoring of performance characteristics to improve processing and properties of polyurethane products requires the selection of efficient catalysts. In flexible foam manufacturing a combination of tin and tertiary amine catalysts are used in order to balance the gelation reaction (urethane formation) and the blowing reaction (urea formation). The tin catalysts used include dibutyltin dilaurate, dibutylbis(laurylthio)stannate, dibutyltinbis(isooctylmercapto acetate), and dibutyltinbis(isooctylmaleate). Strong bases, such as potassium acetate, potassium 2-ethylhexoate, or amine–epoxide combinations are the most useful trimerization catalysts.

The formation of cellular products also requires surfactants to facilitate the formation of small bubbles necessary for a fine-cell structure. The most effective surfactants are polyoxyalkylene–polysiloxane copolymers. The physical properties of polyurethanes are derived from their molecular structure and determined by the choice of building blocks as well as the supramolecular structures caused by atomic interaction between chains. The ability to crystallize, the flexibility of the chains, and spacing of polar groups are of considerable importance, especially in linear thermoplastic materials. In rigid cross-linked systems, e.g., polyurethane foams, other factors such as density determine the final properties.

Thermoplastic Polyurethanes. The unique properties of polyurethanes are attributed to their long-chain structure. In segmented polyether- and polyesterurethane elastomers, hydrogen bonds form between −NH−groups (proton donor) and the urethane carbonyl, polyether oxygen, or polyester carbonyl groups. The symmetrical MDI is more suitable for the preparation of segmented polyurethane elastomers having excellent physical properties. Segmented polyurethanes are also obtained from 2,6-TDI, but an economically attractive separation process for the TDI isomers has yet to be developed.

The melt viscosity of a thermoplastic polyurethane (TPU) depends on the weight-average molecular weight and is influenced by chain length and branching. TPUs are viscoelastic materials, which behave like a glassy, brittle solid, an elastic rubber, or a viscous liquid, depending on temperature and time scale of measurement. With increasing temperature, the material becomes rubbery because of the onset of molecular motion. At higher temperatures a free-flowing liquid forms. The melt temperature of a polyurethane is important for processibility. Melting should occur well below the decomposition temperature.

Thermoset Polyurethanes. The physical properties of rigid urethane foams are usually a function of foam density. A change in strength properties requires a change in density. Rigid polyurethane foams that have densities of <0.064 g/cm^5, used primarily for thermal insulation, are expanded with HCFCs, HFCs, or hydrocarbons. See also **Insulation (Thermal)**. Often water or a carbodiimide catalyst is added to the formulation to generate carbon dioxide as a coblowing agent. In addition to density, the strength of a rigid foam is influenced by the catalyst, surfactant, polyol, isocyanate, and the type of mixing. By changing the ingredients, foams can be made that have high modulus, low elongation, and some brittleness (friability), or relative flexibility and low modulus. See also **Foamed Plastics**.

The properties of thermoset flexible polyurethane foams are also related to density; load-bearing properties are likewise important. Under normal service temperatures, flexible foams exhibit rubber-like elasticity to deformations of short duration, but creep under long-term stress. Maximum tensile strength is obtained at densities of ca 0.024–0.030 g/cm^3 · g/cm^3. The densities are controlled by the amount of water in the formulation and may range from 0.045 to 0.020 g/cm^3 by raising the amount of water from 2 to 5%. Auxiliary blowing agents are also used to reduce density and control hardness. The size and uniformity of the cells are controlled by the efficiency of mixing and the nucleation of the foam mix.

Hyperbranched polyurethanes are constructed using phenol-blocked trifunctional monomers in combination with 4-methylbenzyl alcohol for end capping. Polyurethane interpenetrating polymer networks (IPNs) are mixtures of two cross-linked polymer networks, prepared by latex blending, sequential polymerization, or simultaneous polymerization. IPNs have improved mechanical properties, as well as thermal stabilities, compared to the single cross-linked polymers. In pseudo-IPNs, only one of the involved polymers is cross-linked. Numerous polymers are involved in the formation of polyurethane-derived IPNs.

Raw Materials

Isocyanates. The commodity isocyanates TDI and PMDI are most widely used in the manufacture of urethane polymers. See also **Isocyantes, Organic**. The former is an 80:20 mixture of 2,4- and 2,6-isomers, respectively; the latter a polymeric isocyanate obtained by phosgenation of aniline–formaldehyde-derived polyamines. A coproduct in the manufacture of PMDI is 4, 4′-methylenebis(phenyl isocyanate) (MDI). The manufacture of TDI involves the dinitration of toluene, catalytic hydrogenation to the diamines, and phosgenation. Separation of the undesired 2,3-isomer is necessary because its presence interferes with polymerization. Polymeric isocyanates (PMDI) are crude products that vary in exact composition. The basic raw materials for the manufacture of PMDI and its coproduct MDI is benzene. Nitration and hydrogenation affords aniline (see **Amines; Aromatic Compound**). Reaction of aniline with formaldehyde in the presence of hydrochloric acid gives rise to the formation of a mixture of oligomeric amines, which are phosgenated to yield PMDI. The coproduct, MDI, is obtained by continuous thin-film vacuum distillation.

Urethanes obtained from aromatic diisocyanates undergo slow oxidation in the presence of air and light, causing discoloration, which is unacceptable in some applications. Polyurethanes obtained from aliphatic diisocyanates are color-stable, although it is necessary to add antioxidants and uv-stabilizers to the formulation to maintain the physical properties with time. The least costly aliphatic diisocyanate is hexamethylene diisocyanate (HDI). Isophorone diisocyanate (IPDI) and its derivatives are also used in the formulation of rigid coatings; hydrogenated MDI (HMDI) and cyclohexane diisocyanate (CHDI) are used in the formulation of flexible coatings and polyurethane elastomers.

Masked or blocked diisocyanates are used in coatings applications. The blocked diisocyanates are storage-stable, nonvolatile, and easy to use in powder coatings. Blocked isocyanates are produced by reaction of the diisocyanate with blocking agents such as caprolactam, 3,5-dimethylpyrazole, phenols, oximes, acetoacetates, or malonates.

Polyether Polyols. Polyether polyols are addition products derived from cyclic ethers (Table 1). The alkylene oxide polymerization is usually initiated by alkali hydroxides, especially potassium hydroxide. In the base-catalyzed polymerization of propylene oxide, some rearrangement occurs to give allyl alcohol.

Polyether polyols are high molecular weight polymers that range from viscous liquids to waxy solids, depending on structure and molecular weight. Most commercial polyether polyols are based on the less expensive ethylene or propylene oxide or on a combination of the two. Block copolymers are manufactured first by the reaction of propylene glycol with propylene oxide to form a homopolymer.

With amine initiators the so-called self-catalyzed polyols are obtained, which are used in the formulation of rigid spray foam systems. The rigidity or stiffness of a foam is increased by aromatic initiators, such as Mannich bases derived from phenol, phenolic resins, toluenediamine, or methylenedianiline (MDA). In the manufacture of highly resilient flexible foams and thermoset RIM elastomers, graft or polymer polyols are used.

Polyester Polyols. Polyester polyols are based on saturated aliphatic or aromatic carboxylic acids and diols or mixtures of diols. The carboxylic acid of choice is adipic acid because of its favorable cost/performance ratio. For elastomers, linear polyester polyols of ca 2000 mol wt are preferred. Branched polyester polyols, formulated from higher functional glycols, are used for foam and coatings applications. Phthalates and terephthalates are also used.

In addition, polyester polyols are made by the reaction of caprolactone with diols. Poly(caprolactone diols) are used in the manufacture of thermoplastic polyurethane elastomers with improved hydrolytic stability. The hydrolytic stability of the poly(caprolactone diol)-derived TPUs is comparable to TPUs based on the more expensive long-chain diol adipates. Polyether/polyester polyol hybrids are synthesized from low molecular weight polyester diols, which are extended with propylene oxide.

Uses

Flexible Foam. Flexible slab or bun foam is poured by multicomponent machines at rates of >45 kg/min. One-shot pouring from traversing mixing heads is generally used. A typical formulation for furniture-grade foam having a density of 0.024 g/cm^3 includes a polyether triol, mol wt 3000; TDI; water; catalysts, i.e., stannous octoate in combination with a tertiary amine; and surfactant. Coblowing agents are often used to lower the density of the foam and to achieve a softer hand. Coblowing agents are methylene chloride, methyl chloroform, acetone, and CFC 11, but the last has been eliminated because of its ozone-depletion potential. Additive systems and new polyols are being developed to achieve softer low density

TABLE 1. COMMERCIAL POLYETHER POLYOLS

Product	Nominal functionality	Initiator	Cyclic ether[a]
poly(ethylene glycol) (PEG)	2	water or EG	EO
poly(propylene glycol) (PPG)	2	water or PG	PO
PPG/PEG[b]	2	water or PG	PO/EO
poly(tetramethylene glycol)	2	water	THF
glycerol adduct	3	glycerol	PO
trimethylolpropane adduct	3	TMP	PO
pentaerythritol adduct	4	pentaerythritol	PO
ethylenediamine adduct	4	ethylenediamine	PO
phenolic resin adduct	4	phenolic resin	PO
diethylenetriamine adduct	5	diethylenetriamine	PO
sorbitol adduct	6	sorbitol	PO/EO
sucrose adduct	8	sucrose	PO

[a] EO = ethylene oxide; PO = propylene oxide; THF = tetrahydrofuran.
[b] Random or block copolymer.

foams. Higher density (0.045 g/cm^3) slab or bun foam, also called high resiliency (HR) foam, is similarly produced, using polyether triols having molecular weight of 6000. The use of polymer polyols improves the load-bearing properties.

Flame retardants are incorporated into the formulations in amounts necessary to satisfy existing requirements. There are four main types of flexible slabstock foam: conventional, high resiliency, filled, and high load-bearing foam.

Most flexible foams produced are based on polyether polyols; ca 8–10% (15–20% in Europe) of the total production is based on polyester polyols. Flexible polyether foams have excellent cushioning properties, are flexible over a wide range of temperatures, and can resist fatigue, aging, chemicals, and mold growth. Polyester-based foams are superior in resistance to dry cleaning and can be flame-bonded to textiles.

Molded flexible foam products are becoming more popular. The bulk of the molded flexible urethane foam is employed in the transportation industry, where it is highly suitable for the manufacture of seat cushions, back cushions, and bucket-seat padding. TDI prepolymers were used in flexible foam molding in conjunction with polyether polyols. The need for heat curing has been eliminated by the development of cold-molded or high resiliency foams.

Semiflexible molded polyurethane foams are used in other automotive applications, such as instrument panels, dashboards, arm rests, head rests, door liners, and vibrational control devices. An important property of semiflexible foam is low resiliency and low elasticity, which results in a slow rate of recovery after deflection. The isocyanate used in the manufacture of semiflexible foams is PMDI, sometimes used in combination with TDI or TDI prepolymers. Both polyester as well as polyether polyols are used in the production of these water-blown foams.

Rigid Foams. Rigid polyurethane foam is mainly used for insulation. See also **Insulation (Thermal)**. The configuration of the product determines the method of production. Rigid polyurethane foam is produced in slab or bun form on continuous lines, or it is continuously laminated between either asphalt or tar paper, or aluminum, steel, and fiberboard, or gypsum facings. Rigid polyurethane products, for the most part, are self-supporting, which makes them useful as construction insulation panels and as structural elements in construction applications. Polyurethane can also be poured or frothed into suitable cavities, i.e., pour-in-place applications, or be sprayed on suitable surfaces.

Some formulations, particularly those for refrigerator and freezer insulation, are based on modified TDI (golden TDI) or TDI prepolymers, but these are being replaced by PMDI formulations. The polyols used include propylene oxide adducts of polyfunctional hydroxy compounds or amines (Table 1). The amine-derived polyols are used in spray foam formulations where high reaction rates are required. Crude aromatic polyester diols are often used in combination with the multifunctional polyether polyols. Blending of polyols of different functionality, Polyether–polyester polyol hybrids are also synthesized from low mol wt polyesters, which are subsequently propoxylated. Reactive or nonreactive fire retardants, containing halogen and phosphorus, are often added to meet the existing building code requirements. The most commonly used reactive fire retardants are Fyrol 6, chlorendic anhydride-derived diols, and tetrabromophthalate ester diols (PHT 4-Diol). Because the reactive fire retardants are combined with the polyol component, storage stability is important. Nonreactive fire retardants include halogenated phosphate esters, such as tris(chloroisopropyl) phosphate (TMCP) and tris(chloroethyl) phosphate (TCEP), and phosphonates, such as dimethyl methylphosphonate (DMMP). Also used are borax and melamine.

Because of the mandatory phaseout of CFCs by Jan. 1, 1996, it had become necessary to develop blowing agents that have a minimal effect on the ozone layer. As a short-term solution, two classes of blowing agents are considered: hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs). For example, HCFC 141b, CH_3CCl_2F (bp 32°C), is a drop-in replacement for CFC-11, and HFC 134a, CF_3CH_2F (bp −26.5°C), was developed to replace CFC-12. HCFC 142b, CH_3CClF_2 (bp −9.2°C), is the blowing agent used in the 1990s. Addition of water or carbodiimide catalysts to the formulation generates carbon dioxide as a coblowing agent. Longer-range environmental considerations have prompted the use of hydrocarbons such as pentanes and cyclopentane as blowing agents.

From the onset of creaming to the end of the rise during the expansion process, the gas must be retained completely in the form of bubbles, which ultimately result in the closed-cell structure. Addition of surfactants facilitates the production of very small uniform bubbles necessary for a fine-cell structure. The catalysts used in the manufacture of rigid polyurethane foams include tin and tertiary amine catalysts. Many of the rigid insulation foams produced in the 1990s are urethane-modified isocyanurate (PUIR) foams. In the formulation of poly(urethane isocyanurate) foams an excess of PMDI is used. The isocyanate index can range from 105 to 300 and higher. PUIR foams have a better thermal stability than polyurethane foams.

The formation of isocyanurates in the presence of polyols occurs via intermediate allophanate formation, i.e., the urethane group acts as a cocatalyst in the trimerization reaction. By combining cyclotrimerization with polyurethane formation, processibility is improved, and the friability of the derived foams is reduced. Modification of cellular polymers by incorporating amide, imide, oxazolidinone, or carbodiimide groups has been attempted but only the urethane-modified isocyanurate foams are produced in the 1990s. PUIR foams often do not require added fire retardants to meet most regulatory requirements. A typical PUIR foam formulation is shown in Table 2.

CASE Polyurethanes. CASE is the acronym for coatings, adhesives, sealants, and elastomers. Polyurethane coatings are mainly based on aliphatic isocyanates and acrylic or polyester polyols because of their outstanding weather-ability. For flexible elastomeric coatings, HMDI and IPDI are used with polyester polyols, whereas higher functional derivatives of HDI and IPDI with acrylic polyols are mainly used in the formulation of rigid coatings. Plastics coatings, textile coatings, and artificial leather are based on either aliphatic or aromatic isocyanates. For light-stable textile coatings, combinations of IPDI and IPDA (as chain extender) are used. The poly(urethane urea) coatings are applied either directly to the fabric or using transfer coating techniques. Microporous polyurethane sheets (poromerics) are used for shoe and textile applications. Polyurethane binder resins are also used to upgrade natural leather.

Blocked aliphatic isocyanates or their derivatives are used for one-component coating systems. Masked polyols are also used for this application. Water-borne polyurethane coatings are formulated by incorporating ionic groups into the polymer backbone. These ionomers are dispersed in water through neutralization. Ionic polymers are also formulated from TDI and MDI. Poly(urethane urea) and polyurea ionomers are obtained from divalent metal salts of *p*-aminobenzoic acid, MDA, dialkylene glycol, and 2,4-TDI. Polyurethane adhesives are known for excellent adhesion, flexibility, toughness, high cohesive strength, and fast cure rates. Two-component adhesives consist of an isocyanate prepolymer, which is cured with low equivalent weight diols, polyols, diamines, or polyamines. Such systems can be used neat or as solution. The two components are kept separately before application. Two-component polyurethane systems are also used as hot-melt adhesives.

Water-borne adhesives are preferred because of restrictions on the use of solvents. Low viscosity prepolymers are emulsified in water, followed by chain extension with water-soluble glycols or diamines. As cross-linker PMDI can be used. Water-borne polyurethane coatings are used for vacuum forming of PVC sheeting to ABS shells in automotive interior door panels, for the lamination of ABS/PVC film to treated polypropylene foam for use in automotive instrument panels, as metal primers for steering wheels, in flexible packaging lamination, as shoe sole adhesive, and as tie coats for polyurethane-coated fabrics. PMDI is also used as a binder for reconstituted wood products and as a foundry core binder.

Polyurethane sealant formulations use TDI or MDI prepolymers made from polyether polyols. The sealants contain 30–50% of the prepolymer; the remainder consists of pigments, fillers, plasticizers, adhesion promoters, and other additives.

TABLE 2. TYPICAL PUIR FOAM FORMULATION

Ingredients	Parts
PMDI (250 index)	208.7
Terate 203[a]	100.0

Dabco TMR 30	1.2
surfactant	2.0
HCFC 141b	35.0

[a] Crude aromatic polyester diol.

Polyurethane elastomers are either thermoplastic or thermoset polymers, depending on the functionality of the monomers used. Thermoplastic polyurethane elastomers are segmented block copolymers, comprising of hard- and soft-segment blocks. The soft-segment blocks are formed from long-chain polyester or polyether polyols and MDI; the hard segments are formed from short-chain diols, mainly 1,4-butanediol, and MDI. Thermoset polyurethanes are cross-linked polymers, which are produced by casting or reaction injection molding (RIM). For cast elastomers, TDI in combination with 3, 3′-dichloro-4, 4′-diphenylmethanediamine (MOCA) are often used.

Polyurethane engineering thermoplastics are also manufactured from MDI and short-chain glycols.

Segmented elastomeric polyurethane fibers (Spandex fibers) based on MDI have also been developed.

Recycling. The methods proposed for the recycling of polyurethanes include pyrolysis, hydrolysis, and glycolysis. Regrind from polyurethane RIM elastomers is used as filler in some RIM as well as compression molding applications. The RIM chips are also used in combination with rubber chips in the construction of athletic fields, tennis courts, and pavement of working roads of golf courses.

The use of rebound flexible foam for carpet underlay and for high load-bearing padding for furniture or for gymnasium mats is already a reality. Rebound flexible foam can also be used for sound dampening in cars. Rebounding of rigid foam particles with PMDI produces polyurethane particle boards. These boards are unaffected by water and are therefore used in furniture aboard ships. Rigid foam scrap is also used as filler in the manufacture of building products. The most convenient chemical recycling process, consists of glycolysis of solid polyurethane products. Heating of polyurethane scrap in a mixture of glycols and diethanolamine converts the cross-linked polymers into linear soluble oligomers via a transesterification process.

Health and Safety Factors

Fully cured polyurethanes present no health hazard; they are chemically inert and insoluble in water and most organic solvents. Dust can be generated in fabrication, and inhalation of the dust should be avoided. Polyether-based polyurethanes are not degraded in the human body, and are therefore used in biomedical applications. Some of the chemicals used in the production of polyurethanes, such as the highly reactive isocyanates and tertiary amine catalysts, must be handled with caution. The other polyurethane ingredients, polyols and surfactants, are relatively inert materials having low toxicity.

Isocyanates in general are toxic chemicals and require great care in handling. Respiratory effects are the primary toxicological manifestations of repeated overexposure to diisocyanates.

There are a multitude of governmental requirements for the manufacture and handling of isocyanates. The U.S. EPA mandates testing and risk management for TDI and MDI under Toxic Substance Control Administration (TSCA). Annual reports on emissions of both isocyanates are required by the EPA under SARA 313.

The liquid tertiary aliphatic amines used as catalysts in the manufacture of polyurethanes can cause contact dermatitis and severe damage to the eye. Inhalation can produce moderate to severe irritation.

Polyurethanes can be considered safe for human use. However, exposure to dust, generated in finishing operations, should be avoided. Polyurethanes are combustible. An approved fire-resistive thermal barrier must be applied over foam insulation on interior walls and ceilings. Under no circumstances should direct flame or excessive heat be allowed to contact polyurethane or polyisocyanurate foam.

Commercial Applications

The largest markets for flexible polyurethane foam are in the furniture, transportation, and bedding industries.

The bulk of the rigid polyurethane and polyisocyanurate foam is used in insulation. See also **Insulation (Thermal)**. More than half (60%) of the rigid foam consumed in 1994 was in the form of board or laminate; the remainder was used in pour-in-place and spray foam applications.

Polyurethane surface coatings are used wherever applications require abrasion resistance, skin flexibility, fast curing, good adhesion, and chemical resistance. See also **Coatings**. Synthetic leather products are also produced using a urethane binder. These poromeric materials are produced from textile-length fiber mats impregnated with DMF solutions of polyurethanes. Permeability to moisture vapor is the key property needed in synthetic leather. In addition to shoe applications, poromerics are used for handbags, luggage, and apparel. Polyurethane films having oxygen and water permeability are applied in bandages and wound dressings and as artificial skin for burn victims.

Polyurethane elastomers are used in applications where toughness, flexibility, strength, abrasion resistance, and shock-absorbing qualities are required. Thermoplastic polyurethane elastomers and polyurethane engineering thermoplastics are molded or extruded to produce elastomeric products used as automobile parts, shoe soles, ski boots, roller skate and skateboard wheels, pond liners, cable jackets, and mechanical goods. Cast and RIM elastomers are used in auto fascia, bumper and fender extensions, printing and industrial rolls, industrial tires, and industrial and agricultural parts, such as oil well plugs and grain buckets. Elastomeric spandex fibers are used in hosiery and sock tops, girdles, brassieres, support hose, and swim wear. The use of spandex fibers in sport clothing is increasing.

UREY, HAROLD C. (1894–1981). An American chemist who received the Nobel prize in chemistry in 1934 for his discovery of the heavy isotopes of hydrogen and oxygen. His discovery became and important factor in the development of nuclear fission and fusion and made possible the production of the transuranic element Pu. He was one was one of the leaders of the Manhattan Project, which constructed the first nuclear reactor at the University of Chicago and eventually produced the first atomic bomb. Obtaining his doctorate at the University of California in 1923, he taught at several leading universities, including Columbia where he discovered deuterium D oxide (heavy water), used as a moderator in early types of nuclear reactors. Later he devoted much study to the origin of the universe and the origin of life on earth. He was the author of many scientific treatises and made notable contributions to the cosmological theories.

URINE. The fluid secreted from the blood by the kidneys, stored in the bladder, and discharged by the urethra. In health, it is amber colored. About 1,250 milliliters of urine are excreted in 24 hours by normal humans, with specific gravities usually between 1.018 and 1.024 extremes: 1.003–1.040). Flow ranges from 0.5–20 milliliters/minute with extremes of dehydration and hydration. Maximum osmolar concentration is 1,400, compared to plasma osmolarity of 300. In diabetes insipidus, characterized by inadequate antidiuretic hormone (ADH) production, volumes of 15–25 liters/day of dilute urine may be formed. In addition to the substances listed in Table 1, there are trace amounts of purine bases and methylated purines, glucuronates, the pigments urochrome and urobilin, hippuric acid, and amino acids. In pathological states, other substances may appear: proteins (nephrosis); bile pigments and salts (biliary obstruction); glucose, acetone, acetoacetic acid and betahydroxybutyric acid (diabetes mellitus). The U/P ratios of the substances in the table vary widely because of differential handling by the kidney. Quantitative knowledge of glomerular filtration, tubular reabsorption, and secretion of these requires an understanding of the concept of renal plasma clearance.

TABLE 1. COMPOSITION OF 24-HOUR URINE IN THE NORMAL ADULT[a]

Substance	Amount (Grams)	U/Pb[b]
Urea	6.0–180.0 (nitrogen)	60.0
Creatinine	0.3–0.8 (nitrogen)	70.0
Ammonia	0.4–1.0 (nitrogen)	—
Uric acid	0.08–0.2 (nitrogen)	20.0
Sodium	2.0–4.0	0.8–1.5
Potassium	1.5–2.0	10.0–15.0
Calcium	0.1–0.3	—
Magnesium	0.1–0.2	—
Chloride	4.0–8.0	0.8–2.0
Bicarbonate	—	0.0–2.0
Phosphate	0.7–1.6 (phosphorus)	25.0
Inorganic sulfate	0.6–1.8 (sulfur)	50.0
Organic sulfate	0.06–0.2 (sulfur)	–

[a]Based upon data by White, Handler, Smith, and Stetten.
[b]U/P ratio = ratio of urinary to plasma concentration.

The rate at which a substance (X) is excreted in the urine is the product of its urinary concentration, U_x (milligram/milliliter), and the volume of urine per minute, V. The rate of excretion ($U_x V$) depends, among other factors, upon the concentration of X in the plasma, P_x (milligram/milliliter). It is therefore reasonable to relate $U_x V$ to P_x and this is called the clearance ratio: $(U_x \cdot V)/P_x$, or more generally, *UV/P*. This has the dimensions of volume and is in reality the smallest volume from which the kidneys can obtain the amount of X excreted per minute. The kidneys do not usually clear the plasma completely of X, but clear a larger volume incompletely. The clearance is therefore not a real, but a virtual volume. When substances are being cleared simultaneously, each has its own clearance rate, depending upon the amount absorbed from the glomerular filtrate or added by tubular secretion. The former will have the lower clearance, the latter the higher. Those cleared only by glomerular filtration will be intermediate, and their clearance will in effect measure the rate of glomerular filtration in milliliters/minute.

The best-known substance that can be infused into blood to provide a clearance equal to glomerular filtration rate is *inulin*, a polymer of fructose containing 32 hexose molecules (molecular weight 5,200). Strong evidence indicates that it is neither reabsorbed nor secreted, is freely filterable, is not metabolized, and has no physiological influences. Its clearance in humans is 120–130 milliliters/minute. This is taken to be the glomerular filtration rate (GFR) or C_F (amount of plasma water filtered through glomeruli/minute). Besides inulin in the dog and other vertebrates, creatinine, thiosulfate, ferrocyanide, and mannitol also fulfill these requirements.

Knowing the glomerular filtration rate permits quantification of the amount of any substance freely filtered (C_F(milliliters/minute) $\times$ P_x(milligrams/milliliter)). Subtracting from this one minute's excretion, $U_x V$, would give the amount reabsorbed in milligrams/minute. A classical example is the glucose mechanism. At normal plasma concentrations, none or a trace appears in the urine. When plasma glucose is elevated to about 180–200 milligram percent (the "threshold"), the amount appearing in the urine begins to increase. As concentration is raised more, the nephrons become progressively saturated until the rate of reabsorption becomes constant and maximal. This indication of saturation of the transport system is referred to as the T_m ("tubular maximum—T_{mG}). In humans, T_{mG} has the value of 340 milligrams/minute. Absorption occurs in the proximal convoluted tubules.

URONIC ACID. Any of a class of compounds similar to sugars but differing from them in that the terminal carbon has bee oxidized from an alcohol to carboxyl group. The most common are galacturonic acid and glucuronic acid.

V

VACCINE TECHNOLOGY. A vaccine is a preparation used to prevent a specific infectious disease by inducing immunity in the host against the pathogenic microorganism. The practice is also called immunization.

With the discovery and widespread use of antibiotics, beginning in the 1950s, the interest in vaccine research disappeared. It was anticipated that infectious diseases would no longer be a threat to human health. This expectation turned out to be too optimistic. Today, there are still numerous infection diseases, for which antibiotic has not been effective. The development of biotechnology and modern immunology created new opportunities for producing new antigens and vaccine research has become a primary focus in recent years. As a result, several vaccines such as Hepatitis B, Hepatitis A, *H. influenza*, and Varicella have been approved. A new vaccine against pertussis has been recently approved in the U.S.

Commercial Vaccines

Vaccines can be roughly categorized into killed vaccines and live vaccines. A killed vaccine can be (*1*) an inactivated, whole microorganism such as pertussis, (*2*) an inactivated toxin, called toxoid, such as diphtheria toxoid, or (*3*) one or more components of the microorganism commonly referred to as subunit vaccines.

Vaccines for human use are regulated by the FDA in the U.S. and Boards of Health in other countries. The manufacturing of vaccines requires adherence to strict current good manufacturing practices (cGMPs) and in the U.S. licenses for both the process and the facility where the vaccine is produced are required. The Center for Biologics Evaluation and Research (CBER); (http://www.fda.gov/cber/) is the branch of the FDA that requlates vaccines. Basic requirements are described in The Code of Federal Regulations (CFR):http://www.gpoaccess.gov/cfr/index.html

Vaccines for the General Population

Vaccines in this category protect children and adults from polio, diphtheria, tetanus, pertussis (whooping cough), measles (rubeola), mumps, rubella (German measles), hepatitis B, and haemophilus disease (meningitis, epiglotitis).

Poliomyelitis. Two vaccines are licensed for the control of poliomyelitis in the United States. The live, attenuated oral polio virus (OPV) vaccine can be used for the immunization of normal children. The killed or inactivated vaccine is recommended for immunization of adults at increased risk of exposure to poliomyelitis and of immunodeficient patients and their household contacts. Both vaccines protect against the three serotypes of poliomyelitis that cause disease.

Diphtheria, Tetanus, and Pertussis. These vaccines in combination (DTP) have been routinely used for active immunization of infants and young children since the 1940s. The recommended schedule calls for immunizations at 2, 4, and 6 months of age with boosters at 18 months and 4–5 years of age. Since 1993 these vaccines have been available in combination with a vaccine that protects against *Haemophilus* disease, thus providing protection against four bacterial diseases in one preparation. A booster immunization with diphtheria and tetanus only is recommended once every 10 years after the fifth dose.

Measles, Mumps, Rubella. Live, attenuated vaccines are used for simultaneous or separate immunization against measles, mumps, and rubella in children from around 15 months of age to puberty. Two doses, one at 12–15 months of age and the second at 4–6 or 11–12 years are recommended in the U.S.

Haemophilus influenza serotype b. Three vaccines are available for immunizing infants. Two of these vaccines are administered at 2, 4, and 6 months of age with a booster given at 12–15 months of age, and the third vaccine is administered at 2 and 4 months of age with a booster at 12–15 months of age.

Hepatitis B. Although Hepatitis B (Hep B) is not an infant disease, it is recommended for infant immunization to better control spread, because compliance with vaccine immunization programs is easier to achieve in an infant population. Infants receive immunizations at birth, 1–2 months, and a third dose at 6 months. Other schedules are available for immunization of adolescents and adults who have not previously received the vaccine.

Varicella. The varicella (chicken pox) vaccine was approved in April 1995 for immunization of children. A single dose at one year of age is recommended. In the future it may be combined with measles, mumps, and rubella.

Vaccines for Special Populations

Two vaccines that are in fairly widespread use in the adult population are vaccines that prevent viral influenza and pneumococcal pneumonia.

Influenza. The ACIP recommends annual influenza vaccination for all persons who are at risk from infections of the lower respiratory tract and for all older persons. Influenza viruses types A and B are responsible for periodic outbreaks of febrile respiratory disease.

Pneumococcal Polysaccharide. Pneumococcal polysaccharide vaccine may be used for immunization of persons two years of age or older who are at increased risk of pneumococcal disease.

Vaccines Being Developed

Despite the tremendous advances since the 1960s in the biomedical fields, there remains a large number of diseases that are endemic in many parts of the world. The Third World or developing countries bear the brunt of several of these, e.g., malaria, trypanosomiasis, and schistosomiasis. In developed countries, diseases such as herpes and gonorrhea are becoming increasingly prevalent. Some of these vaccines have been developed and licensed, whereas good progress is advancing in other areas. In the meantime, emerging exotic viruses such as HIV and drug-resistant pathogens continue to appear. There is an urgent need to expand vaccine R&D.

Meningitis. *Haemophilus influenze*, type b (Hib), *Streptococcus pneumoniae*, and *Neisseria meningitidis* are the major cause of meningitis in infants. Vaccines against Hib disease prepared using conjugate technology have been in use worldwide, and have been efficacious in eliminating the disease from the population. This same technology is being applied to the development of vaccines for *S. pneumoniae* and *N. meningitidis*.

S. pneumoniae has more than 80 sero-types. The current polysaccharide vaccine consists of 23 serotypes and covers about 87% of all pneumococcal diseases in the United States. Current vaccine development is based on conjugate technology and concentrates on the most prevalent 7–9 serotypes. Three multivalent vaccine candidates are in clinical trials. All are based on conjugating the polysaccharide to a T-dependent protein carrier. The results of phase I and II trials in infants have demonstrated the safety and immunogenicity of these vaccines. Phase III trials to demonstrate efficacy are in progress and final approval of this vaccine for infant immunization will be by the year 2000.

N. meningititidis also has several groups and serotypes. Most of the diseases are caused by groups A, B, and C. A multivalent polysaccharide vaccine consisting of types A, C, Y, and W_{135} is available. However, like other polysaccharide vaccines, it is not immunogenic in infants. Conjugate vaccines against groups A and C are being developed, using different protein carries and conjugate chemistries. Clinical trials of these vaccines are in progress.

The capsular polysaccharide of group B meningococcus is not immunogenic in humans. Thus, a conjugate vaccine of the group B polysaccharide will not improve its efficacy, and this remains a major challenge in developing the vaccine against group B organisms.

Rotavirus. Rotavirus causes infant diarrhea, a disease which has major socio-economic impact. In developing countries it is the major cause of death in infants worldwide. In the U.S., diarrhea is still a primary cause of physician visits and hospitalization, although the mortality rate is relatively low. Two membrane proteins (VP4 and VP7) of the virus have been identified as protective epitopes and most vaccine development programs are based on these two proteins as antigens. Both live attenuated vaccines and subunit vaccines are being developed. By using the technique of viral gene re-assortant, a multivalent live attenuated vaccine for rotavirus has been developed. The vaccine candidates are generated by transferring the VP7 gene from a human rotavirus to Rhesus monkey (or bovine) rotavirus. On August 31, 1998 the FDA licensed a tetravalent rhesus rotavirus vaccine for use in infant. It will be well into the twenty-first century before a vaccine will be available.

Respiratory Syncytial Virus. RSV causes severe lower respiratory tract disease in infants. It is the major cause of hospitalization in the U. S. and it has a high mortality rate in neonates and other high risk populations, such as the geriatric population.

Both subunit and live, attenuated vaccine approaches are being developed for RSV. A candidate subunit vaccine based on the surface (F-) protein is being tested. Live attenuated vaccines for RSV are also being developed.

Parainfluenza. Parainfluenza viruses (PIV) also causes viral pneumonia in infants. It is similar to RSV, therefore similar approaches are being used for developing a vaccine. A live attenuated PIV-3 vaccine has been in clinical trial.

Otitis Media. Otitis media is thought to be caused by several bacteria, significantly *S. pneumoniae*, nontypable *H. influenza*, and *Moraxella catarrhalis*. Viruses such as influenza, RSV, and PIV may also play a role in the disease. The use of a pneumococcal vaccine is the first step in the development of an otitis media vaccine. Vaccines against nontypable *H. influenza* and *Moraxella* are at the development stages. Both vaccine candidates are derived from the exposed proteins of the bacteria.

Herpes Simplex. There are two types of herpes simplex virus (HSV) that infect humans. Type I causes orofacial lesions and 30% of the U.S. population suffers from recurrent episodes. Type II is responsible for genital disease and anywhere from $3 \times 10^4 - 3 \times 10^7$ cases per year (including recurrent infections) occur. The primary source of neonatal herpes infections, which are severe and often fatal, is the mother infected with type II. In addition, there is evidence to suggest that cervical carcinoma may be associated with HSV-II infection. Vaccine development is hampered by the fact that recurrent disease is common. Thus, natural infection does not provide immunity and the best method to induce immunity artificially is not clear. A much better understanding of the pathogenesis of the virus and virus-host interactions are required for the efficient development of the vaccine.

Influenza. Although current influenza vaccine (subunit split vaccine) has been in use yearly for the elderly, it is not recommended for the general population or infants. Improvements to increase or prolong the immunogenicity, reduce the side-effects (due to egg production procedure), and provide mass protection are still being pursued. One approach is to use a live, attenuated virus though cold adaptation. Subunit vaccines based on the surface proteins of virus are also being explored. It has been demonstrated that the two major protective antigens are haemagglutinin (HA) and neuraminidase (NA). The genes for these antigens have been cloned and expressed in baculovirus in insect cell culture.

Malaria. Malaria infection occurs in over 30% of the world's population and almost exclusively in developing countries. The majority of the disease in humans is caused by four different species of the malarial parasite. Vaccine development is problematic for several reasons. The parasites have a complex life cycle; malaria is difficult to grow in large quantities outside the natural host. Despite these difficulties, vaccine development has been pursued for many years. An overview of the state of the art is available.

Gonorrhea. Gonorrhea, caused by *Neisseria gonorrheae*, is the most commonly reported communicable disease in the United States. An increasing number of strains are becoming resistant to penicillin, the antibiotic that is usually used to treat this disease. Development of a vaccine is problematic because natural infection does not necessarily provide immunity. Studies are being carried out on various structural components of the gonococcal bacterium, including pili, outer membrane proteins, lipopolysaccharide, and the outer capsule, in an effort to develop a vaccine. One of the more promising approaches involves a vaccine made with pili. Human studies indicate that a pili vaccine stimulates antibody formation that is 50–100 times the prevaccination level and is effective in preventing disease after challenge.

Human Immunodeficiency Virus. HIV causes Acquired Immunodeficiency Syndrome (AIDS). HIV infects the cells of the human immune system, such as T-lymphocytes, monocytes, and macrophages. After a long period of latency and persistent infection, it results in the progressive decline of the immune system, and leads to full-blown AIDS, resulting in death.

The development of vaccine against HIV-1 has been a top priority of the national public health agencies and medical research institutes. The effort in developing a vaccine has not been as successful as expected. The main problem is the tremendous antigenic variability of the virus. An antigen derived from the cultured strain might not be the same as the clinical strain. Another problem is the fact that the virus infects the cells of the human immune system, making the design of the vaccine more complex. It will require certain combinations of immune responses to provide long-term protection or eliminate the virus from the host. So far, the proper immune mechanism for achieving this goal has not been identified, although it is generally agreed that a cell-mediated immune response (CMI) is essential. Up to the 1990s, most of the vaccine candidates have been derived from the surface proteins of the virus. Although these candidates all show immunogenicity and are protective in animal models, clinical studies of these proteins have not been able to demonstrate protection against disease. Efforts in development of the vaccine are being continued in the public and private research institutes.

Other Vaccines

There are many other diseases which do not have effective vaccines. These diseases are mostly regional in nature, epidemic in the developing world. Vaccines against parasites are also becoming critical to public health. Vaccines are being developed for Lyme disease, dengue, *Helicobacter pylori*, Japanese encephalitis, Equine encephalitis, Tickborne encephalitis, cholera, shigellas, schistosomiasis, group B streptococcus, and other sexually transmitted diseases.

Future Technology

Vaccines for many diseases are unavailable because of an inability to determine the appropriate method for vaccination or difficulty in obtaining large quantities of antigens. Advances in medical science and immunology have substantially improved the understanding of the design and delivery of antigens. Genetic engineering offers further advances in providing the techniques for construction and production of large quantities of antigens. Development of these fields has been responsible for the rapid advances of vaccinology. Development of new vaccines also requires different process technology for the production of antigens and preparation of delivery system for vaccines.

Genetic Engineering. Genetic engineering involves preparation of DNA fragments (passengers) coding for the substance of interest, inserting the DNA fragments into vectors (cloning vehicles), and introducing the recombinant vectors into living host cells where the passenger DNA fragments replicate and are expressed, i.e., transcribed and translated, to yield the desired substance.

Since the 1970s, genetic engineering has evolved to become the most powerful and routine tool in the study of immunology and the development of new vaccines. It offers new, and in some instances safer and more effective methods for production of vaccines of higher quality. It has allowed an efficient way for the study of construction of new attenuated live viral or bacterial vaccines. It can also be used to study the pathogenicity and immunology of viruses or bacteria. Recombinant hepatitis B vaccine is the first approved human vaccine based on a genetic engineering technique. The genetic engineering techniques can also be used to reduce the virulence of a pathogen which can then be used to produce vaccines. Live vectors are another application of genetic engineering. In this case, the genes from a pathogen are inserted into a vaccine vector, such as salmonella or vaccinia.

The use of naked DNA as a vaccine is the most recent development in this field. Since the demonstration of the possibility of genetic immune response by direct injection of DNA into muscle cells, the field is developing rapidly. Clinical trials for influenza, hepatitis, HIV-1, and herpes simplex are being initiated.

Adjuvants. Adjuvants are substances which can modify the immune response of an antigen. With better understanding of the functions of different arms of the immune system, it is possible to explore the effects of an adjuvant, such that the protective efficacy of a vaccine can be improved. At present, aluminum salt is the only adjuvant approved for use in human vaccines.

Peptide Vaccines. Development of a peptide vaccine is derived from the identification of the immunodominant epitope of an antigen. A polypeptide based on the amino acid sequence of the epitope can then by synthesized. Preparation of a peptide vaccine has the advantage of allowing for large-scale production of a vaccine at relatively low cost. It also allows for selecting the appropriate T- or B-cell epitopes to be included in the vaccine, which may be advantageous in some cases.

Process Technology

In the preparation of classical killed or toxoid vaccines, simple process technology was used. With the advance of new vaccines, far more sophisticated process technologies are needed. The desire to reduce side effects of vaccination requires processes which will yield antigens of extreme purity. The new regulation in cGMP requires consistent production procedures, and global competition also demands that the most efficient process technology be applied.

The basic process technology in vaccine production consists of fermentation for the production of antigen, purification of antigen, and formulation of the final vaccine. In bacterial fermentation, technology is well established. For viral vaccines, cell culture is the standard procedure. Different variations of cell line and process system are in use. For most of the live viral vaccine and other subunit vaccines, production is by direct infection of a cell substrate with the virus. Alternatively, some subunit viral vaccines can be generated by rDNA techniques and expressed in a continuous cell line or insect cells.

Development of conjugate and peptide vaccines requires the typical organic synthesis process and purification. This is a new area for vaccine technologists. Again, the main concern is to maintain the immunogenicity of the vaccine candidate during the chemical reaction and purification steps. Most of these procedures are proprietary.

Economic Aspects

Costs of vaccine manufacture vary according to the type of vaccine produced and how it is supplied. Live virus vaccines are generally less expensive because the quantitative mass to be given to the recipient is less than an inactivated or subunit vaccine. The purification process and yield and the number of strains or components in any given vaccine also affect the cost of manufacture. New vaccines often have a royalty cost, in addition to manufacturing and testing costs. Filling and packaging is often the most expensive part of the manufacturing process and the cost varies by how many doses are filled and packed into one unit.

Another important aspect of vaccine technology is the cost–benefit relationship between prevention vaccination and disease treatment. Generally the cost savings are high.

Liability for adverse reaction events associated in time with immunization have also played a principal role in vaccine economics. Prior to 1988, compensation for any adverse reaction associated in time with vaccination required that the vaccine recipient bring suit against the manufacturer or the health care provider that administered the vaccine. The uncertainty of numbers and costs associated with lawsuits contributed to the decline in the number of providers of routine childhood vaccines. The enactment in 1988 of the National Vaccine Injury Compensation Program was provided as a nonfault alternative to the tort system for resolving claims resulting from adverse reactions to mandated childhood vaccines, and has achieved its goal of providing compensation to those injured by rare adverse events associated with vaccination and providing some stability for the vaccine market.

VACUUM. According to definition, a space entirely devoid of matter. The term is used in a relative sense in vacuum technology to denote gas pressures below the normal atmosphere pressure of 760 torr (1 torr = 1 millimeter of mercury). The degree or quality of the vacuum attained is indicated by the total pressure of the residual gases in the vessel that is pumped. Table 1 shows generally accepted terminology for denoting various degrees of vacuum, together with pertinent pressure ranges; the calculated molecular density (from the equation $p = nkT$, where p is the pressure n is the molecular density, i.e., number of molecules per cubic centimeter; k is the Boltzmann's constant; and T is the absolute temperature taken to be 293 K (20°C); and the mean free path λ from the approximate equation for air: $\lambda = 5/p$ centimeters, where p is the pressure in millitorr).

In the quantum field theories that describe the physics of elementary particles, the vacuum becomes somewhat more complex than previously defined. Even in empty space, matter can appear spontaneously as a result of fluctuations of the vacuum. It may be pointed out, for example, that an electron and a positron, or antielectron, can be created out of the void. Particles created in this way have only a fleeting existence; they are annihilated almost as soon as they appear, and their pressure can never be detected directly. They are called *virtual particles* in order to distinguish them from real particles. Thus, the traditional definition of vacuum (space with no real particles in it) holds. In their excellent paper, the aforementioned authors discuss how, near a superheavy atomic nucleus, empty space may become unstable, with the result that matter and antimatter can be created without any input of energy. The process may soon be observed experimentally.

Even when all matter and heat radiation have been removed from a region of space, the vacuum of classical physics remains filled with a distinctive pattern of electromagnetic fields. The discovery of a connection between thermal radiation and the structure of the classical vacuum reveals

TABLE 1. VARIOUS QUALITIES OF VACUUM AND PRESSURE RANGES

Quality of vacuum	Pressure range (torr)	Molecular density, n (molecules/cubic centimeter)	Mean free path, λ (centimeters)
Coarse or rough vacuum	760–1	2.69×10^{19}–3.5×10^{16}	6.6×10^{-6}–5×10^{-3}
Medium vacuum	1–10^{-3}	3.5×10^{16}–3.5×10^{13}	5×10^{-3}–5
High vacuum	10^{-3}–10^{-7}	3.5×10^{13}–3.5×10^{9}	5–5×10^{4}
Very high vacuum	10^{-7}–10^{-9}	3.5×10^{9}–3.5×10^{7}	5×10^{4}–5×10^{6}
Ultrahigh vacuum	$<10^{-9}$	$<3.5 \times 10^{7}$	$>5 \times 10^{6}$

an unexpected unity in the laws of physics, but it also complicates the view of what was once considered simply *empty space*. But, even with its pattern of electric and magnetic fields, the vacuum remains the simplest state of nature. Perhaps this statement reflects more on the subtlety of nature than it does on the simplicity of the vacuum.

Vacuum Pumps

Two widely used vacuum pumps are the mechanical rotary oil-sealed pump and the vapor pump. The former provides a medium vacuum and works relative to the atmosphere. The vapor pump, on the other hand, provides a high or very high vacuum and operates relative to a medium vacuum provided by a rotary pump, referred to as a backing pump in this connection. Thus, the most widely used high-vacuum system able to establish an ultimate pressure of about 10^{-6} torr or below consists of a vapor pump backed by a rotary pump.

Several patterns of rotary oil-sealed pumps exist, but they have in common the fact that the volume between a rotor (or rotating plunger) and a stator is divided into two crescent-shaped sections, which are isolated from one another as regards the passage of gas. Further, they are furnished with an intake port and a discharge outlet valve to the atmosphere. One revolution of the rotor (speeds of 450 to 700 revolutions per minute are used), gas is swept from the intake port, compressed, and discharged to the atmosphere via the one-way outlet valve. The mechanism is immersed in a low-vapor-pressure oil for sealing and lubrication in a small pump; larger units have a separate oil reservoir and feed device. A spring-loaded vane type of rotary oil-sealed pump is shown in Fig. 1. A single-stage pump of this kind provides an ultimate pressure of about 10^{-2} torr; a two-stage one with two units in cascade will give an ultimate of about 10^{-4} torr. Rotary pumps with speeds from 20 to 20,000 liters/minute are commercially available, the smallest being driven by an 1/8-hp motor, the largest requiring a 40-hp motor.

These pumps handle permanent gases efficiently. Condensable vapors, e.g., water vapor, are not satisfactorily pumped because they may liquefy during the compression part of the rotation. To prevent this, gas ballast is a common provision whereby air from the atmosphere is admitted to the pump through a simple, adjustable screw valve to the region between the rotor and stator just before the discharge outlet valve. The amount of extra air admitted is readily adjusted to provide a compressed gas-vapor mixture, which opens the discharge valve before vapor condensation occurs. Gas ballasting will clearly increase significantly the ultimate pressure provided by the pump, but this is not important since the gas-ballast valve can be closed after initial pumping has removed most of the water vapor.

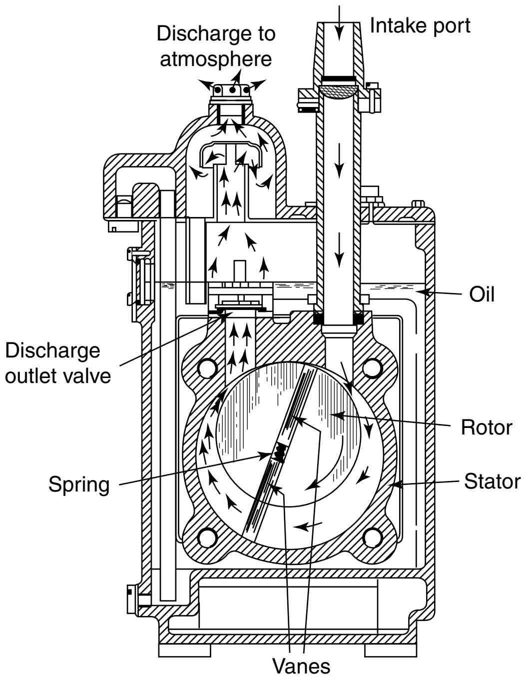

Fig. 1. Spring-loaded vane-type rotary oil-sealed vacuum pump

Vapor pumps are of two main types: vapor diffusion pumps and vapor ejector pumps. Both employ vapor (of either mercury or a low-vapor-pressure oil) issuing from a jet as a means of driving gas in the direction from the intake port to the discharge outlet, which is maintained at a medium vacuum by a backing rotary pump. In the diffusion pump (a two-stage design utilizing oil as the pump fluid), the vapor issuing from the top, first-stage jet is directed downward towards the backing region. Gas molecules from the intake port diffuse into the streaming vapor. The directed oil molecules collide with the gas molecules to give them velocity components toward the backing region. A large pressure gradient is thereby established in the pump so that the intake pressure may be over 100,000 times less than the backing pressure. The intake pressure may therefore be 10^{-6} torr or lower with a backing pressure of 10^{-1} torr.

In the diffusion pump, the vapor stream is not essentially influenced by the gas pumped. In the vapor ejector pump, however, the vapor stream is enabled by a higher boiler pressure to be denser and of greater speed with a higher intake pressure, so that the gas is entrained by the high-speed vapor. Viscous drag and turbulent mixing now carry the gas at initially supersonic speeds down a pump housing of diminishing cross section. The ejector pump is designed to operate with a maximum pumping speed at an intake pressure of 10^{-1} to 10^{-3} torr and with a backing pressure of 0.5 to 1 torr or more. The diffusion pump, on the other hand, is designed to have a fairly constant speed from 10^{-3} torr down to an ultimate 10^{-6} torr or much lower in a modern, bakeable stainless steel system.

An important mechanical pump, which operates in the same pressure region as the oil ejector, is the Roots pump, capable of very great speeds and requiring backing by a rotary oil−sealed pump.

A vacuum system may consist of a diffusion pump and a backing pump, together with baffles, cold traps and isolation valves. The cold trap is essential if a mercury vapor diffusion pump is used and is best filled with liquid nitrogen (−196°C); otherwise, the system will be exposed to the mercury vapor pressure, which is 10^{-3} torr at 18°C.

Ultrahigh-vacuum systems with stainless steel traps and metal sealing gaskets, and bakeable (except for the pumps) for several hours to 450°C, may be constructed to provide an ultimate pressure of 10^{-9} to 10^{-10} torr.

Other vacuum pumps include the sorption type based on the high gas take-up of charcoal or molecular sieve material at liquid nitrogen temperatures. Sorption pumps may be used in place of rotary pumps, with a desirable freedom from rotary pump oil vapor, especially in systems where the amount of gas to be handled is limited.

The chief rival to the vapor diffusion pump at present is the getterion pump of the Penning discharge type, sometimes called the sputter-ion pump, with electrodes of titanium metal. The principle of operation is illustrated by Fig. 2 where an egg-box type anode is situated between plane cathodes. The anode-cathode operating potential difference is of the order of 2 to 10 kV, and the magnetic flux density is about 3,000 gauss. The chief pumping action with active gases such as hydrogen, nitrogen and oxygen is to the anode which receives deposited titanium (which has very high gas affinity) sputtered from the cathodes under the action of the positive ion bombardment. Some gas, especially the inert gases like argon, is pumped to the cathodes.

A typical multicell pump of moderate size of this type has a pumping speed of about 250 liters/second. Much larger pumps with speeds of up to 5,000 liters/second are commercially available, as are small single-cell units with speeds of some 2 liters/second.

The sputter-ion pumps provide a vapor-free system giving a so-called dry vacuum, and they are often incorporated in plant with molecular sieve sorption as the backing pump. For medium-size laboratory plant able to provide ultrahigh vacuum they are most attractive. Probably their chief

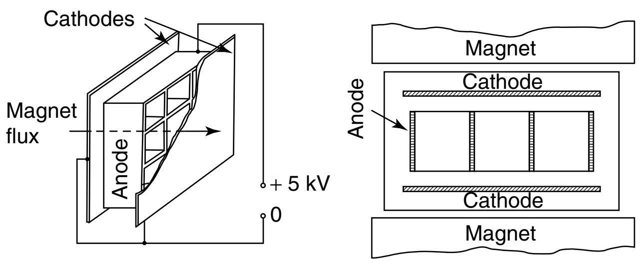

Fig. 2. Sputter-ion vacuum pump

disadvantage is that the life of the pump is only about 40 hours at 10^{-3} torr, but this increases inversely with the pressure, so that it is 40,000 hours at 10^{-6} torr. At present, they are therefore strong rivals to the diffusion pump for plant where moderate amounts of gas are handled in the lower pressure ranges.

In cryogenic pumping, the provision is, within an initially evacuated system, a surface which is at such a low temperature that gas impinging on the surface will be condensed. For example, if the surface is maintained at the temperature of liquid helium (−269°C), all other gases have insignificantly low vapor pressures at this temperature and molecules of these gases impinging on the surface would remain there. A pumping speed for nitrogen of nearly 12 liters sec^{-1} cm^{-2} of cooled surface is hence theoretically possible. Liquid nitrogen, together with molecular sieve and other sorbent surfaces, and also liquid-hydrogen (−253°C, at which the vapor pressure of solid nitrogen is 10^{-10} torr) and liquid-helium cooled metallic surfaces, are being actively investigated for the possibility of providing very high pumping speeds (10^6 liters/sec is not out of question) in space simulators and other plants.

Vacuum Measurement

Subatmospheric pressure usually is expressed in reference to perfect vacuum or absolute zero pressure. Like absolute zero temperature (the concept is analogous), absolute zero pressure cannot be achieved, but it does provide a convenient reference datum. Standard atmospheric pressure is 14.695 psi absolute, 30 inches of mercury absolute, or 760 mmHg of density 13.595 g/cm^3 where acceleration due to gravity is $g = 980.665$ cm/s^2. 1 mmHg, which equals 1 torr, is the most commonly used unit of absolute pressure. Derived units, the million or micrometer, representing 1/1000 of 1 mmHg or 1 torr, are also used for subtorr pressures.

In the MKS system of units, standard atmospheric pressure is 750 torr and is expressed as 100,000 Pa (N/m^2) or 100 kPa. This means that 1 Pa is equivalent to 7.5 millitorr (1 torr = 133.3 pascal). Vacuum, usually expressed in inches of mercury, is the depression of pressure below the atmospheric level, with absolute zero pressure corresponding to a vacuum of 30 inches of mercury.

When specifying and using vacuum gages, one must constantly keep in mind that atmospheric pressure is *not* constant and that it also varies with elevation above sea level.

Vacuum gages can be either direct or indirect reading. Those that measure pressure by calculating the force exerted by incident particles of gas are direct reading, while instruments that record pressure by measuring a gas property that changes in a predictable manner with gas density are indirect reading.

The range of operation for these two classes of vacuum instruments is given in Table 2. Since the pressure range of interest in present vacuum technology extends from 760 to 10^{-13} torr (over 16 orders of magnitude), there is no single gage capable of covering such a wide range. The ranges of vacuum where specific types of gages are most applicable are shown in Fig. 3.

TABLE 2. RANGE OF OPERATION OF MAJOR VACUUM GAGES

Principle	Gage type	Range, torr
Direct reading	Force measuring:	
	Bourdon, bellows, manometer (oil and mercury),	$760–10^{-6}$
	McLeod capacitance (diaphragm)	760×10^{-6}
Indirect reading	Thermal conductivity:	
	Thermocouple (thermopile)	$10–10^{-3}$
	Pirani (thermistor)	$10–10^{-4}$
	Molecular friction	$10^{-2}–10^{-7}$
	Ionization:	
	Hot filament	$10–10^{-10}$
	Cold cathode	$10^{-2}–10^{-15}$

The operating principles of some vacuum gages, such as liquid manometers, bourdon, bellows, and diaphragm gages involving elastic members, were described earlier in this article. The remaining vacuum measurement devices include the thermal conductivity (or Pirani and thermocouple-type gages), the hot-filament ionization gage, the cold-cathode ionization gage (Philips), the spinning-rotor friction gage, and the partial-pressure analyzer.

Pirani or Thermocouple Vacuum Gage. Commercial thermal conductivity gages ordinarily should not be considered as precision devices. Within their rather limited but industrially important pressure range, they are outstandingly useful. The virtues of these gages include low cost, electrical indication readily adapted to remote readings, sturdiness, simplicity, and interchangeability of sensing elements. They are well adapted for uses where a single power supply and measuring circuit is used with several sensing elements located in different parts of the same vacuum system or in several different systems.

The working element of the gages consists of a metal wire or ribbon exposed to the unknown pressure and heated by an electric current. See Fig. 4. The temperature attained by the heater is such that the total rate of heat loss by radiation, gas convection, as thermal conduction, and thermal conduction through the supporting leads equals the electric power input to the element. Convection is unimportant and can be disregarded, but the heat loss by thermal conduction through the gas is a function of pressure. At pressures of approximately 10 torr and higher, the thermal conductivity of a gas is high and roughly independent of further pressure increases. Below about 1 torr, on the other hand, the thermal conductivity decreases with decreasing pressure, eventually in linear fashion, reaching zero at zero pressure. At pressures above a few torr, the cooling by thermal conduction limits the temperature attained by the heater to a relatively low value. As the pressure is reduced below a few hundred millitorr, the heater temperature rises, and at the lowest pressures, the heater temperature reaches an upper value established by heat radiation and by thermal conduction through the supporting leads.

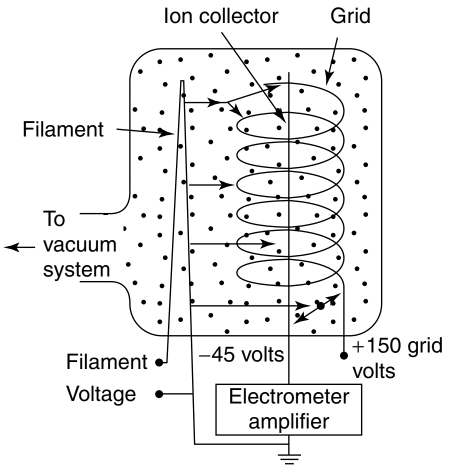

Fig. 5. Hot-filament ionization gage. (*Bayard-Alpert type*)

Hot-Filament Ionization Vacuum Gage. This gage is the most widely used pressure-measuring device for the region from 10^{-2} to 10^{-11} torr. The operating principle of this gage is illustrated in Fig. 5.

A regulated electron current (typically about 10 mA) is emitted from a heated filament. The electrons are attracted to the helical grid by a dc potential of about +150 volts. In their passage from filament to grid, the electrons collide with gas molecules in the gage envelope, causing a fraction of them to be ionized. The gas ions formed by electron collisions are attracted to the central ion collector wire by the negative voltage on the collector (typically −30 volts). Ion currents collected are on the order of 100 mA/torr. This current is amplified and displayed using an electronic amplifier.

This ion current will differ for different gases at the same pressure—that is, a hot-filament ionization gage is composition-dependent. Over a wide range of molecular density, however, the ion current from a gas of constant composition will be directly proportional to the molecular density of the gas in the gage.

Cold-Cathode Ionization Vacuum Gage. This ingenious gage, in vented by Penning, possesses many of the advantages of the hot-filament ionization gage without being susceptible to burnout. Ordinarily, an electrical discharge between two electrodes in a gas cannot be sustained below a few millitorr pressure. To simplify a complicated set of relationships, this is because the "birthrate" of new electrons capable of sustaining ionization is smaller than the "death rate" of electrons and ions. In the Philips gage this difficulty is overcome by the use of a collimating magnetic field, which forces the electrons to traverse a tremendously increased path length before they can reach the collecting electrode. In traversing this very long path, they have a correspondingly increased opportunity to encounter and ionize molecules of gas in the interelectrode region, even though this gas may be extremely rarefied. It has been found possible by this use of a magnetic field and appropriately designed electrodes, as indicated in Fig. 6, to maintain an electric discharge at pressures below 10^{-9} torr.

Comparison with the hot-filament ionization gage reveals that, in the hot-filament gage, the source of the inherently linear relationship between gas pressure (more exactly molecular density) and gage reading is the fact that the ionizing current is established and regulated independently of the resulting ion current. In the Philips gage this situation does not hold. Maintenance of the gas discharge current involves a complicated set of interactions in which electrons, positive ions, and photoelectrically effective x-rays all play a significant part. It is thus not surprising that the output current of the Philips gage is not perfectly linear with respect to pressure. Slight discontinuities in the calibration are also sometimes found, since the magnetic fields customarily used are too low to stabilize the gas discharge completely. Despite these objections, a Philips gage is a highly useful device, particularly where accuracy better than 10 or 20% is not required.

The Philips gage is composition-sensitive, but, unlike the situation with the hot-filament ionization gage, the sensitivity relative to some reference gas, such as air or argon, is not independent of pressure. Leak hunting with a Philips gage and a probe gas or liquid is a useful technique. Unlike the hot-filament ionization gage, the Philips gage does not involve the use of a high-temperature filament and consequently does not subject the gas to thermal stress. The voltages applied in the Philips gage are on the order of a few thousand volts, which is sufficient to cause some sputtering at the high-pressure end of the range. This results in a certain amount of gettering or enforced takeup of the gas by the electrodes and other part of the gage. Various design refinements have been used to facilitate periodic cleaning of the vacuum chamber and electrodes, since polymerized organic molecules are an ever-present contaminant.

The conventional cold-cathode (Philips) gage is used in the range from 10^{-2} to 10^{-7} torr. Redhead has developed a modified cold-cathode gage useful in the 10^{-6} to 10^{-12} torr range. See Fig. 7. The operating voltage is about 5000 volts in a 1-kG magnetic field.

Spinning-Rotor Friction Vacuum Gage. Although liquid manometers (U-tube, McLeod) serve as pressure standards for subatmospheric measurements (760 to 10^{-5} torr), and capacitance (also quartz) manometers duplicate this range as useful transfer standards, calibration at lower pressures depends on both volume expansion techniques and presumed linearity of the measuring system. The friction gage allows extension of the calibration range directly down to 10^{-7} torr. It measures pressure in a vacuum system by sensing the deceleration of a rotating steel ball levitating in a magnetic field. See Fig. 8.

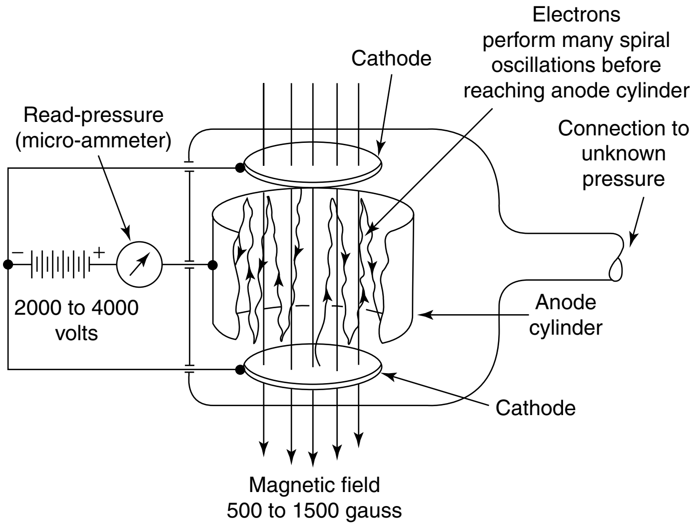

Fig. 6. Philips cold-cathode ionization vacuum gage

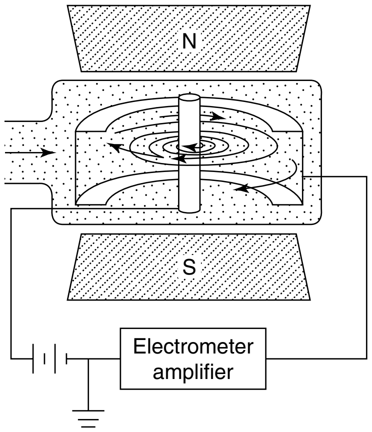

Fig. 7. Inverted magnetron, a cold-cathode gage, produces electrons by applying a high voltage to unheated electrodes. Electrons spiraling in toward the central electrode ionize gas molecules, which are collected on the curved cathode

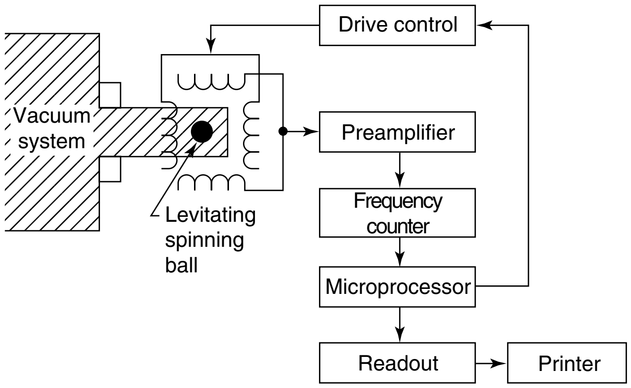

Fig. 8. Schematic diagram of spinning-rotor friction gage

TABLE 3. CHARACTERISTICS OF PARTIAL-PRESSURE ANALYZERS

Type	Minimum partial pressure, torr	Resolution,* au	Magnetic field
Magnetic sector	10^{-11}	20–150	Yes
Cycloidal	10^{-11}	100–150	Yes
Quadrupole	10^{-12}	100–300	No
Time of flight	10^{-12}	200	No

*Maximum mass number at which a mass number difference of 1 can be observed.

Partial-Pressure (Residual Gas) Analyzers. Many applications of high-vacuum technology are more concerned with the partial pressure of particular gas species than with total pressure. Also, "total" pressure gages generally give accurate readings only in pure gases. For these reasons partial-pressure analyzers are finding increasing application. These are basically low-resolution, high-sensitivity mass spectrometers that ionize a gas sample in a manner similar to that of a hot-filament ionization gage. The resulting ions are then separated in an analyzer section, depending on the mass-to-charge ratio of each ion. The ion current corresponding to one ion type is then collected, amplified, and displayed. Partial-pressure gages are very valuable diagnostic tools in both research and production work. The major types are listed in Table 3.

VACUUM DEPOSITION. The process of coating a base material by evaporating a metal under high vacuum and condensing it on the surface of the material to be coated, which is usually another metal or a plastic. Aluminum is most commonly used for this purpose. The coatings obtained range in thickness from 0.01 to as many as 3 mils. A vacuum of about one-millionth atmosphere is necessary. The process is used for jewelry, electronic components, decorative plastics, etc. Thermally evaporated metals and dielectric coatings can be effectively applied to glass by this method. It is also called vacuum coating and vacuum metallizing.

See also **Thin Films**.

VACUUM DISTILLATION. Distillation at pressure below atmospheric but not so low that it would be classed as molecular distillation. Since lowering the pressure also lowers the boiling point, vacuum distillation is useful for distilling high-boiling and heat-sensitive materials such as heavy distillates in petroleum, fatty acids, vitamins, etc.

See also **Petroleum**.

VALENCE. A whole number that represents of denotes the combining power of one element with another. By balancing these integral valence numbers in a given compound, the relative proportions of the elements present can be accounted for. If hydrogen and chlorine both have a valence of 1, oxygen a valence of 2, and nitrogen3, the valence-balancing principle gives the formulas HCl, H_2, NH_3, CI_2O, NCI_3, and N_2O_3, which indicate the relative numbers of atoms of these elements in compounds that they form with each other. In inorganic compounds it is necessary to assign either a positive or negative value to each valence number, so that valence balancing will give a zero sum by algebraic addition. Negative numbers are called polar valence numbers (−1 and −2). The valence of chlorine may be −1, +1, +3, +5, or +7, depending on the type of compound in which it occurs. In organic chemistry only nonpolar valence numbers are used.

VANADINITE. The mineral vanadinite corresponds to the formula $Pb_5(VO_4)_3Cl$, being composed of lead chloride and lead vanadate in the proportion of 90.2% of the former and 9.8% of the latter. It crystallizes in the hexagonal system, is usually prismatic, but the crystals are often skeletal or cavernous; it may be found in crusts. Its fracture is uneven; brittle; hardness, 2.75–3; specific gravity, 6.86; fresh fractures show a resinous luster; color, yellow, yellowish-brown, reddish-brown, and red; streak, white to yellowish; translucent to opaque. Vanadinite, not a common mineral, occurs as an alteration product in lead deposits. It is found in the Ural Mountains, Austria, Spain, Scotland, Morocco, the Transvaal, Argentina, and Mexico. In the United States it occurs in Arizona, New Mexico, and South Dakota. It is used as an ore of vanadium and to some extent of lead as well. It is interesting to note that this mineral was first described as a chromate upon its discovery in Mexico in 1801. It was not until the discovery of the element vanadium in 1830 that the true nature of this compound was known.

VANADIUM. [CAS: 7440-62-2]. Chemical element symbol V, at. no. 23, at. wt. 50.942, periodic table group 5, mp 1880–2000°C, bp 3380°C, density 6.10 g/cm^3. Elemental-vanadium has a body-centered cubic crystal structure. Vanadium is a silver-white, very hard (7 on the Mohs scale), oxidizes upon exposure to air, burns upon ignition to form the pentoxide V_2O_5, insoluble in HCl, slowly dissolves in hydrofluoric, HNO_3, or H_2SO_4 (hot, concentrated), or aqua regia. Insoluble in HaOH solution. The element was first reported by Andrés Manuel del Rio in 1801; later and separately reported by Nils Gabriel Sefstr "om in 1830. There are two naturally occurring isotopes ^{50}V (radioactive and with a half-life something greater than 10^{14} years and only present to the extent of 0.24% in natural substances) and ^{51}V (99.76 abundance percentage). Five other radioactive isotopes have been identified ^{46}V through ^{49}V and ^{52}V. ^{49}V has a half-life of 330 days. ^{48}V has a half-life of 16.1 days; the others have half-lives measured in seconds or minutes. Vanadium ranks 22nd among chemical elements occurring in the Earth's crust. An average composition of igneous rocks contains 0.017% V. It is estimated that vanadium occurs in seawater to the extent of about 9.5 tons per

cubic mile (2.1 metric tons per cubic kilometer). First ionization potential 6.74 eV; second, 14.7 eV; third 29.6 eV; fourth 48.3 eV; fifth, 68.64 eV. Oxidation potentials: $V \longrightarrow V^{2+} + 2e^-$, 1.5 V, $V^{2+} \longrightarrow V^{3+} + e^-$, 0.255 V, $VO^{2+} + H_2O \longrightarrow VO_2{}^+ + 2H^+ + e^-$, −1.00 V. Electronic configuration $1s^22s^22p^63s^23p^63d^34s^2$.

Other important physical characteristics of vanadium are given under **Chemical Elements**.

Vanadium occurs as patronite, containing vanadium pentasulfide, in Peru, as carnotite, potassium uranyl vanadate, in Colorado and Utah, as vanadinite, lead vanadate, in Arizona, New Mexico, the Republic of South Africa and Zambia. See also **Carnotite**; and **Vanadinite**. Ships burning Venezuelan or Mexican petroleum fuel oil recover vanadium oxide from the boiler and stack dust. In Italy the refining of bauxite ore (for aluminum) yields vanadium, and in Germany some iron ores contain vanadium. Vanadium and radium ore is found in southwestern Colorado and southeastern Utah; in Arizona a complex ore of gold, silver, and lead contains vanadium and molybdenum; and extensive deposits of phosphate rock in Idaho yield tonnage quantities of vanadium. The sulfide ore is roasted to remove sulfur, and the residue fused with sodium carbonate, forming sodium vanadate. This last is extracted with H_2O and excess of H_2SO_4 is added, causing precipitation of vanadium pentoxide, which is later reduced by carbon or aluminum at high temperatures.

Physical Properties

Some properties of selected vanadium compounds are listed in Table 1. Vanadium, a typical transition element, displays well-characterized valence states of 2–5 in solid compounds and in solutions. Valence states of −1 and 0 may occur in solid compounds. All compounds of vanadium having unpaired electrons are colored, but because the absorption spectra may be complex, a specific color does not necessarily correspond to a particular oxidation state.

Uses

Most vanadium produced is consumed as ferrovanadium. Ferrovanadium is made by the aluminum or silicon reduction of the oxide in the presence of iron in an electric-arc furnace. The product contains about 85% vanadium, 12% carbon, and 2% iron. Ductile vanadium metal also is produced in significant quantities, mainly by the calcium reduction of the oxide in a process developed by McKechnie and Seybolt. Pure vanadium oxide, calcium metal, and iodine are charged into a heavy-walled steel cylinder, excluding all moisture. After evacuation, heat is applied to initiate the reaction. Molten droplets of vanadium collect beneath the calcium oxide-calcium iodide slag and there form a single button or regulus. Ductile vanadium metal produced in this manner has an analysis of 99.7% vanadium, 0.10% oxygen, 0.04% nitrogen, 0.008% hydrogen, 0.04% iron, and 0.03% carbon. The metal is soft and ductile, can be hot- and cold-worked easily. Any heating must be done in vacuum or an inert atmosphere because the metal oxidizes readily. With exception of HNO_3, the metal withstands other acids and aerated saltwater better than most stainless steels. It has a comparatively low cross section for neutron capture and is of interest in the nuclear field. The density is 22% less than iron and 28% greater than titanium. The coefficients of thermal and electrical conductivity are higher than those of titanium.

TABLE 1. PHYSICAL PROPERTIES OF SOME INDUSTRIAL AND OTHER SELECTED VANADIUM COMPOUNDS[a]

Compound	CAS Registry number	Formula	Appearance	Mol wt	Density, g/cm^3	Mp, °C	Bp, °C	Solubility
vanadic acid, meta	[13470-24-1]	HVO_3	yellow scales	99.95				soluble in acid and alkali
ammonium metavanadate	[7803-55-6]	NH_4VO_3	white–yellowish or colorless crystals	116.98	2.326	200 dec		slightly soluble in H_2O
potassium metavanadate	[13769-43-2]	KVO_3	colorless crystals	134.04				soluble in hot H_2O
sodium metavanadate	[13718-26-8]	$NaVO_3$	colorless, mono-clinic prisms	121.93		630		soluble in H_2O
sodium orthovanadate	[13721-39-6]	Na_3VO_4	colorless, hex-agonal prisms	183.94		850–856		soluble in H_2O
sodium pyrovanadate	[13517-26-5]	$Na_4V_2O_7$	colorless, hexa-gonal prisms	305.84		632–654		soluble in H_2O
vanadium carbide	[12070-10-9]	VC	black cubic	62.95	5.77	2810	3900	insoluble in H_2O; soluble in HNO_3 with decomposition
vanadium nitride	[24646-85-3]	VN	black cubic	64.95	6.13	2320		soluble in *aqua regia*
vanadium(III) trichloride	[7718-98-1]	VCl_3	pink crystals, deliquescent	157.301	3.00	dec		soluble (deliquescent) in H_2O; soluble in methanol and ether
vanadium(IV) tetrachloride	[7632-51-1]	VCl_4	red-brown liquid	192.75	1.816	28 ± 2	148.5	soluble (deliquescent) in H_2O; soluble in methanol, ether, and chloroform
vanadium(V) oxytrichloride	[7727-18-6]	$VOCl_3$	yellow liquid	173.30	1.829	−77 ± 2	126.7	soluble (deliquescent) in H_2O; soluble in methanol, ether, acetone, and acid
vanadium(II) oxide	[12035-98-2]	VO	light green crystals	66.95	5.758	ignites		soluble in acid
vanadium(III) oxide	[1314-34-7]	V_2O_3	blue crystals	149.88	4.87	1970		soluble in HNO_3, HF, and alkali in presence of oxide
vanadium(IV) oxide	[12036-21-4]	VO_2	blue crystals	82.94	4.339	1967		soluble in acid and alkali
vanadium(V) oxide	[1314-62-1]	V_2O_5	yellow-red rhombohedra	181.88	3.357	690	1750 dec	slightly soluble in H_2O; soluble in acid and alkali
vanadium(IV) disilicide	[12039-87-1]	VSi_2	metallic prisms	107.11	4.42			soluble in HBr
vanadium(III) acetylacetonate	[13476-99-8]	$V(C_5H_7O_2)_3$	brown crystals	348.27	0.9–1.2	178–190		soluble in methanol, acetone, benzene, and chloroform
biscyclopentadienyl-vanadium chloride	[12083-18-6]	$(C_5H_5)_2VCl_2$	pale green crystals	252.04		<250 dec		soluble in methanol and chloroform

[a] Ref. 2. *Kirk–Othmer Encyclopedia of Chemical Technology*.

Most vanadium is used by the steel industry. The addition of vanadium to steel causes the formation of vanadium carbide. The carbides are very hard and wear-resistant; they maintain a fine dispersion. The addition of very small quantities (0.02–0.08%) of vanadium enhances strength and toughness of the resulting steel. Many structural, plate, bar, and pipe steels contain vanadium in these amounts. For little additional cost, in comparison with plain carbon steels, there is a marked increase in performance, including higher strength in the as-rolled condition without heat treatment. Often, manganese and copper are added in small quantities along with the vanadium. Some sheet steels that are used for deep-drawing as in auto and home-appliance parts contain vanadium to suppress aging. For such steels, ferrovanadium is added to rimming steels, resulting in a good, nonaging, deep-drawing steel at a smaller cost than for aluminum-killed deep-drawing steel. Some large steel forgings contain vanadium to the extent of 0.5 to 0.15% with the object of improving the mechanical properties of the forgings. Vanadium is particularly effective in raising the strength and ductility of large steel castings and forgings when added in a small percentage. A large number of tool steels contain vanadium to the extent of 0.10 to 5.00%. In these steels, vanadium insures the retention of hardness and cutting ability at the high temperatures resulting from the rapid cutting of metals. The use of vanadium in cast iron controls the size and distribution of graphite flakes and thus improves strength and wear resistance. One of the most popular of the titanium-base alloys contains 4% vanadium and 6% aluminum. The addition ingredient for this titanium alloy, produced in large quantities, is a base 40:60 vanadium-alloy.

The use of certain vanadium compounds as catalysts has been increasing. Vanadium oxytrichloride is a catalyst in making ethylene-propylene rubber. Ammonium metavanadate and vanadium pentoxide are used as oxidation catalysts, particularly in the production of polyamides, such as nylon, in the manufacture of H_2SO_4 by the contact process, in the production of phthalic and maleic anhydrides, and in numerous other oxidation reactions, such as alcohol to acetaldehyde, anthracene to anthraquinone, sugar to oxalic acid, and diphenylamine to carbazole. Vanadium compounds have been used for many years in the ceramics field for enamels and glazes. Colors are produced by various combinations of vanadium oxide and silica, zirconia, zinc, lead, tin, selenium, and cadmium. Vanadium intermediate compounds also are used in the making of aniline black used by the dye industry.

Chemistry and Compounds

The common oxidation states are: vanadous, V^{2+}, vanadic, V^{3+}, vanadyl, VO^{2+} or VO^{3+}; pervanadyl, $VO_2{}^+$; metavanadate, $VO_3{}^+$. There are also orthovanadates, $VO_4{}^{3-}$, pyrovanadates, $V_2O_7{}^{4-}$; and complex polyvanadates. The latter group includes di, tri-, tetra-, and octavanadates. The hexavanadates are regarded as oxyvanadium(V) pentavanadates, containing the group $V_5O_{16}{}^{7-}$. Vanadium ions also form heteropolyacids with acids of molybdenum, tungsten, arsenic, phosphorus, silicon and tin. The peroxy vanadium ions include the diperoxoortho-vanadate ions $[VO_2(O_2)_2]^{3-}$ and the peroxovanadium(V) ions, $[V(O_2)]^{3+}$.

Among the simpler compounds of vanadium are the following:

Fluorides: Vanadium trifluoride VF_3, green crystalline solid; vanadium tetrafluoride VF_4, brownish-yellow crystalline solid; vanadium pentafluoride VF_5, brownish-yellow crystalline solid, sublimes on heating.

Chlorides: Vanadium dichloride VCl_2, green crystalline solid, a strong reducing agent; vanadium trichloride VCl_3, pink crystalline solid; vanadium tetrachloride VCl_4, reddish-brown liquid, bp 148°C.

Bromide: Vanadium tribromide VBr_3, green crystalline solid.

Iodides: Vanadium diiodide VI_2, usually hydrated, green crystalline solid; vanadium triiodide VI_3, brown crystalline solid.

Oxyhalides of vanadium are common, including VOF_2, VOF_3, VOCl, $VOCl_2$, $VOCl_3$, VOBr and $VOBr_3$.

Hydroxides: Vanadium dihydroxide $V(OH)_2$, brown precipitate by reaction of NaOH solution with hypovanadous acid (one of the most powerful of reducing agents) lavender solution; vanadous hydroxide $V(OH)_3$, green precipitate by reaction of NaOH solution with vanadous salt, green solution.

Oxides: Vanadium monoxide VO, gray solid; vanadium trioxide V_2O_3, black solid; vanadium dioxide VO_2, dark blue solid; vanadium pentoxide V_2O_5, orange to red solid. The last is the most important oxide; formed by the ignition in air of vanadium sulfide, or other oxide, or vanadium; used as a catalyzer, e.g., the reaction SO_2 gas plus oxygen of air to form sulfur trioxide, and the oxidation of naphthalene by air to form phthalic anhydride.

Bismuth vanadate, $BiVO_4$, exhibits a ferroelastic-paraelastic phase transition and has been the object of considerable investigation. Lattice dimensions of the compound have been determined under numerous different high-pressure or high-temperature conditions and all confirm this transition. R.M. Hazen and J.W.E. Mariathasan, key investigators in this area, have suggested that *in situ* determination of lattice parameters and crystal structures at combined temperature and pressure should be especially valuable in the documentation of nonquenchable, reversible phase transitions, such as that displayed by bismuth vanadate.

Sulfides: Vanadium monosulfide VS; vanadium trisulfide V_2S_3, most stable; vanadium pentasulfide V_2S_5.

Biological Systems: Very little is known of what roles V may play in biological systems. In 1984, scientists at the University of British Columbia found that vanadates stimulate glucose oxidation and transport in adipocytes, enhance glycogen synthesis in liver and diaphragm, and inhibit hepatic glucogenesis and intestinal glucose transport. Working with diabetic rats, the investigators found that vanadates appear to control the high blood glucose and prevent the decline in cardiac performance due to diabetes.

Health, Safety, and Environmental Considerations

Although most foods contain low concentrations of vanadium (<1 ng/g), food is the major source of exposure to vanadium for the general population. High air concentrations of vanadium occur in the occupation setting during boiler-cleaning operations as a result of the presence of vanadium oxides in the dust. The lungs absorb soluble vanadium compounds V_2O_5 well, but the absorption of vanadium salts from the gastrointestinal tract is poor. The excretion of vanadium by the kidneys is rapid with a biological half-life of 20–40 hours in the urine. Vanadium is probably an essential trace element, but a vanadium-deficiency disease has not been identified in humans. The estimated daily intake of the US population ranges from 10–60 micrograms V. Vanadyl sulfate is a common supplement used to enhance weight training in athletes at doses up to 60 mg/d. In vitro and animal studies indicate that vanadate and other vanadium compounds increase glucose transport activity and improve glucose metabolism. In general, the toxicity of vanadium compounds is low. Pentavalent compounds are the most toxic and the toxicity of vanadium compounds usually increases as the valence increases

Most of the toxic effects of vanadium compounds result from local irritation of the eyes and upper respiratory tract rather than systemic toxicity. The only clearly documented effect of exposure to vanadium dust is upper respiratory tract irritation characterized by rhinitis, wheezing, nasal hemorrhage, conjunctivitis, cough, sore throat, and chest pain. Case studies have described the onset of asthma after heavy exposure to vanadium compounds, but clinical studies to date have not detected an increased prevalence of asthma in workers exposed to vanadium.

VAN DER WAALS EQUATION. A form of the equation of state, relating the pressure, volume, and temperature of a gas, and the gas constant. Van der Waals applied corrections for the reduction of total pressure by the attraction of molecules (effective at boundary surfaces) and

for the effect of reduction of total volume by the volume of the molecules (but not the actual molecular volume). The equation takes the form

$$\left(P + \frac{a}{V^2}\right)(V - b) = RT$$

in which P is the pressure of the gas, V is the volume, T is the absolute temperature, R is the gas constant, and a and b are correction terms which have been evaluated and reported for many gases. See also **Characteristic Equation**.

VAN DER WAALS FORCES. Interatomic or intermolecular forces of attraction due to the interaction between fluctuating dipole moments associated with molecules not possessing permanent dipole moments. These dipoles result from momentary dissymmetry in the positive and negative charges of the atom or molecule, and on neighboring atoms or molecules. These dipoles tend to align in antiparallel direction and thus result in a net attractive force. This force varies inversely as the seventh power of the distance between ions.

VAN DER WAALS, JOHANNES DIDERIK (1837–1923). Van der Waals was a Dutch physicist, he was a professor of physics at the University of Amsterdam from 1877 to 1907. He was especially interested in thermodynamics and he won the 1910 Nobel Laureate in Physics for his work on gases and liquids, his most well known expressed as Van der Waals Equation. He also studied the attractive forces, which hold the atoms of molecules together and is named now Van der Waals forces. Van der Waals bonding, a crystalline structure with the weakest bonding, is also named in his honor.

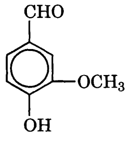
J.M.I.

VANILLIN. Vanillin, [CAS: 121–35–5]. $C_8H_8O_3$, a natural product, can be found as a glucoside (glucovanillin) in vanilla beans, at concentrations of about 2%. It can be extracted with water, alcohol, or other organic solvents. Approximately 250 by-products have been identified in natural vanilla, out of which 26 are present at levels in excess of 1 ppm. The balance of all these products contributes to the subtle taste of vanilla beans. The vanilla bean contains about 2% vanillin, but the 10% extract prepared from beans has several times the strength of a solution of 2% vanillin. The best known natural source of vanillin is the vanilla plant, *Vanilla planifolia* A., which belongs to the orchid family. It is cultivated mainly in Mexico, Madagascar, Reunion, Java, and Tahiti.

The long and expensive process of extracting vanillin from vanilla beans yields a product that has an inconsistent quality. The demand for this universally popular flavoring cannot be satisfied by vanilla beans alone. The consumption of naturally occurring vanilla has gradually given way to synthetic vanillin. Synthetic vanillin is identical to that contained in the pod, but differs in smell and flavor from natural vanillin as a result of the various compounds in the natural extract that do not exist in artificial vanillin. These other compounds represent only 2% of the extract; the remaining 98% is vanillin. Vanillin is the common name for 3-methoxy-4-hydroxybenzaldehyde (**1**).

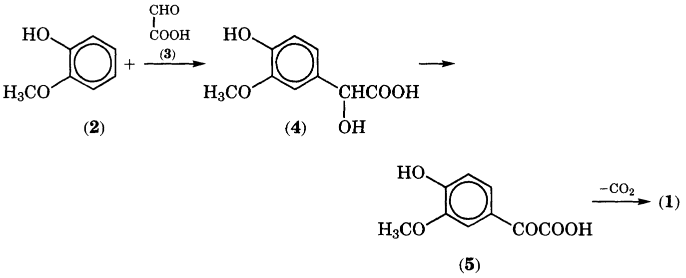


(**1**)

Production

The manufacture of vanillin shows the progress made in the chemistry and chemical engineering of the substance. Most commercial vanillin is synthesized from guaiacol; the remainder is obtained by processing waste sulfite liquors. Preparation by oxidation of isoeugenol is of historical interest only.

Preparation from Guaiacol and Glyoxylic Acid. Several methods can be used to introduce an aldehyde group into an aromatic ring. Condensation of guaiacol (**2**) with glyoxylic acid (**3**), followed by oxidation of the resulting mandelic acid (**4**) to the corresponding phenylglyoxylic acid (**5**) and decarboxylation continues to be a competitive industrial process for vanillin synthesis.



Preparation from Waste Sulfite Liquors. The starting material for vanillin production can also be the lignin present in sulfite wastes from the cellulose industry. The concentrated mother liquors are treated with alkali at elevated temperature and pressure in the presence of oxidants. The vanillin formed is separated from the by-products, particularly acetovanillone, 4-hydroxy-3-methoxyacetophenone, by extraction, distillation, and crystallization. In contrast to vanillin from lignin, the principal impurity found in vanillin from guaiacol is 5-methyl vanillin, typically present at levels of about 100 ppm, although levels as high as 3000 ppm have been found. This impurity is completely odorless.

No residual guaiacol can be found in vanillin produced by the guaiacol process. In contrast to vanillin from lignin, vanillin from guaiacol is extremely consistent in quality owing to the consistency of the supply source, and shows no variation in taste, odor, or color.

Specifications

The physical properties of Rhovanil Extra Pure vanillin of Rhône-Poulenc, the leading company in this area, are shown in Table 1.

Solubility. Solubility in water is less than 2%; the solubility in ethanol, is given by the ratio one part vanillin to two parts alcohol. Certain manufacturing processes require that the product be in liquid form.

Particle-Size Distribution. Particle size, crystal shape, and distribution of vanillin are important and greatly affect parameters such as taste, flavor, solubility, ease of dispersion in solvent, flowability of the powder, caking effect, and production of dust.

Taste and Flavor. The taste effect is generally sweet, but depends strongly on the base of preparation. For tasting purposes, vanillin is often evaluated in ice-cold milk with about 12% sugar. A concentration of 50 ppm in this medium is clearly perceptible. Vanilla is undoubtedly one of the most popular flavors; its consumption in the form of either vanilla extracts or vanillin is almost universal. The food flavor industry is the largest user of vanillin, an indispensable ingredient in chocolate, candy, bakery products, and ice cream. It is easy to smell a difference in the quality of vanillins from different origins, but it is normally difficult to taste the same difference, provided the various samples are of good quality.

Available Grades. Rhovanil Extra Pure is the trade name of the food-grade vanillin of Rhodia, worldwide leader in the diphenols area. The following grades are commercially available: Rhovanil Extra Pure crystallized, Rhovanil Fine Mesh, Rhovanil Free Flow, and Rhovanil Liquid.

Rhovanil Extra Pure is the standard mesh, multipurpose quality of food-grade extra pure vanillin. Rhovanil Fine Mesh, a specially calibrated extra pure vanillin that avoids demixing with other very fine dry ingredients such

[b] At normal pressure.

as sucrose, flour, and dextrose, provides a faster dissolution rate at lower stirring, at lower temperature, in low acidity medium, or in viscous liquids.

Rhovanil Free Flow is obtained by adding an anticaking agent (0.5% max) to the extra pure vanillin. The flowability is increased, making it particularly suitable for self-dispensing equipment (instant beverage), while both mixability and dispersion/dissolution ratios remain as good as the standard Rhovanil Extra Pure vanillin.

Chemical Properties

Vanillin is a compound that possesses both a phenolic and an aldehydic group. It is capable of undergoing a number of different types of chemical reactions. Addition reactions are possible owing to the reactivity of the aromatic nucleus. On distillation at atmospheric pressure, vanillin undergoes partial decomposition with the formation of pyrocatechol. Exposure to air causes vanillin to oxidize slowly to vanillic acid. Reduction of vanillin by means of platinum black in the presence of ferric chloride gives vanillin alcohol in excellent yields. Because vanillin is a phenol aldehyde, it is stable to autooxidation and does not undergo the Cannizzarro reaction. All three functional groups in vanillin are highly reactive.

Applications

In flavor formulations, vanillin is used widely either as a sweetener or as a flavor enhancer, not only in imitation vanilla flavor, but also in butter, chocolate, and all types of fruit flavors, root beer, cream soda, etc. It is widely acceptable at different concentrations; 50–1000 ppm is quite normal in these types of finished products. Concentrations up to 20,000 ppm, i.e., one part in fifty parts of finished goods, are also used for direct consumption such as toppings and icings. Ice cream and chocolate are among the largest outlets for vanillin in the food and confectionery industries, and their consumption is many times greater than that of the perfume and fragrance industry.

When vanillin is not used as a single flavoring ingredient, it is a key part of flavor compounding. At least 30% of food-grade vanillin consumed in the world is through flavoring compounds.

In the industrial production of dry cookies, cakes, and pastries, the vanillin content ranges between 20 and 50 g per 100 kg of dough. Often, vanillin is added at the dry stage of dough preparation as the flour and sugar are being mixed. In fat-free recipes, it is possible to add and mix vanillin powder with eggs.

Vanillin is added, in powder form during the manufacturing process of chocolate, in average amounts of 20 g per 100 kg of the finished product. However, this amount varies according to the quality of the chocolate being made.

Main applications in confections are sugared almonds, caramel, nougat, and sweets. For sugared almonds and caramel, vanillin is mixed into the sugar in the dry phase of the recipe. For nougat, Vanillin is added during the liquid phase of manufacturing. In sweets, vanillin is added in the form of a 10% ethanol solution. Vanillin is used in flavored milk, desserts, yogurts, sorbets, and ice cream.

Vanillin sugar is prepared by dry mixing or impregnating the sugar with a vanillin alcohol solution and evaporating the alcohol. Vanillin confers a pleasant note to liqueur flavoring and improves the flavor of fortified wines by giving them a greatly enhanced bouquet. Vanillin is used as a palatability enhancer to make animal feed more appetizing by flavor-masking minerals with off-taste. Vanillin, a crystal, is the main constituent of the vanilla bean. Its importance can be illustrated by the fact that human preferences in fragrances and in flavors, as determined by various studies, comprise three main smells or tastes: rose, vanilla, and strawberry. Vanillin is used in perfumes and cosmetics as a fragrance and as a washing deodorant.

A flaked technical-grade vanillin, Vaniltek, to be used in pharmaceutical applications. The single largest use for vanillin is as a starting material for the manufacture of an antihypertensive drug having the chemical name of Methyldopa or L-3(3,4-dihydroxyphenyl)-2-methylalanine. Other drugs made from vanillin include L-Dopa, Trimethoprim Mebeverine, and Verazide for example.

Vanillin itself has some bacteriostatic properties and therefore has been used in formulations to treat dermatitis. Hydrazones of vanillin have been shown to have a herbicidal action similar to that of 2,4-D, and the zinc salts of dithiovanillic acid. A new potential use for vanillin is as a ripening agent to increase the yield of sucrose in sugarcane by the treatment of the cane crop a few weeks before harvest.

The antiultraviolet protection properties of vanillin have been patented and look promising for the plastics and cosmetics (suncreams) industries.

Health and Safety Factors

Vanillin is listed in the *Code of Federal Regulations* by the FDA as a Generally Recognized As Safe (GRAS) substance. The Council of Europe and the FAO/WHO Joint Expert Committee on Food Additives have both given vanillin an unconditional Acceptable Daily Intake (ADI) of 10 mg/kg.

Vanillin has a low potential for acute and chronic toxicity. Vanillin is known to cause allergic reactions in people previously sensitized to balsam of Peru, benzoic acid, orange peel, cinnamon, and clove, but vanillin itself is not an allergic sensitizer. Vanillin has been reported to be a bioantimutagen, demonstrating the ability to protect against mutagenic effects by enhancement of an error-free post-replication repair pathway.

VAN SLYKE REACTION. See **Amino Acids**.

VAN'T HOFF EQUATION. A relationship representing the variation with temperature (at constant pressure) of the equilibrium constant of a gaseous reaction in terms of the change in heat content, i.e., of the heat of reaction (at constant pressure). It has the form:

$$\frac{d \ln K_p}{dT} = \frac{\Delta H}{RT^2}$$

in which K_p is the equilibrium constant at constant pressure, T is absolute temperature, R is the gas constant, and ΔH is the standard change in heat content, or, for ideal gases, the change in heat content.

VAN'T HOFF, JACOBUS HENDRICUS (1852–1911). Van't Hoff was born in Rotterdam, the Netherlands. In 1869 he entered the Polytechnic School at Delft and obtained his technology diploma in 1871. His decision to follow a purely scientific career, however, came soon afterwards during vacation–work at a sugar factory when he anticipated for himself a dreary profession as a technologist. After having spent a year at Leyden, mainly for mathematics, he went to Bonn to work with A.F. Kekulé from autumn 1872 to spring 1873. This period was followed by another in Paris with A. Wurtz, when he attended a large part of the curriculum for 1873–1874. He returned to Holland in 1874 and received his Ph.D. from the University of Utrecht under E. Mulder. He did research on chemical dynamics and equilibrium. He was awarded the first Nobel Prize in Chemistry in 1901.

In his later years, Van't Hoff spent his research time trying to understand the action of enzymes as biological catalysts.

J.M.I.

VAN'T HOFF LAW. A dissolved substance has the same osmotic pressure as the gas pressure it would exert in the form of an ideal gas occupying the same volume as that of the solution.

VAPOR. A substance in the gaseous state, but below its critical temperature, is called a vapor. If a pure liquid partly filling a closed container is allowed to stand, the space above it becomes filled with the vapor of the liquid, which then develops a pressure. This vapor pressure increases up to a certain limit, depending upon the temperature, where it becomes constant, and the space is then said to be saturated.

Such a body of vapor is not subject to all of the laws of gases. If the space occupied by it is diminished without change of temperature, there is no increase in pressure, but instead part of the vapor condenses. And if the temperature is raised, the pressure goes up not at a uniform but at an increasing rate, because of both the expansion of the liquid and the further evaporation from it. The relation of vapor to liquid takes on a curious aspect as the critical state is approached, in which the vapor and the liquid have equal density.

See also **Boiling Point**; and **Supersaturated Vapor**.

VAPOR DENSITY. The density of a gas referred to the density of hydrogen or air as unity. If the density of hydrogen is taken as 2, the vapor density is approximately the molecular weight; if it is taken as one, the vapor density equals about half the molecular weight.

VAPORIZATION. The change of a substance from the liquid or solid state to the gaseous state.

VAPORIZATION (Heat of). The evaporation of a given mass of any liquid requires a definite quantity of heat, dependent upon the liquid and upon the temperature at which it evaporates. The quantity required per unit mass at a fixed temperature is called the heat of vaporization of the substance at that temperature. It may be measured by allowing the vapor to condense in a suitable calorimeter, the heat thus evolved, corrected for fall of temperature before and after condensation, being observed. (The heat evolved in condensing is equal to that absorbed when the liquid evaporates.) The result is often surprising. For example, the evaporation of water at the boiling point requires about 540 calories per gram, or more than five times the heat required to raise its temperature from freezing to boiling. The explanation is the large amount of energy necessary to separate the molecules against their cohesion, and the much smaller amount (about 7.4% of the whole) which is used in expanding the vapor against atmospheric pressure. At lower temperatures the value is still greater, because the cohesion is then more effective; with water, for each degree below the normal boiling point, about 0.6 calorie per gram must be added to the heat of vaporization. Trouton found that the heat of vaporization per mole for different liquids bears a nearly constant ratio to the absolute temperature of the boiling point.

A number of methods have been developed for measuring the heat of vaporization. In the Awberg and Griffith's method, the flow is continuous; the heat of evaporation of the liquid under investigation is transmitted to a stream of water flowing at constant rate and its increase in temperature is measured.

VAPOR PRESSURE. The vapor pressure of a substance (solid or liquid) is the pressure exerted by its vapor when in equilibrium with the substance. For pure substances it depends only on the temperature. The simplest way to measure the vapor pressure of a substance is to introduce a small amount of it into the closed end of a barometer tube and note the decrease in the height of the barometer.

The vapor pressure of a solvent is lowered on dissolving the solute in it. This lowering for dilute solutions is proportional to the mole fraction of the solute (Raoult's Law). The lowering of the vapor pressure of the solution can be related to the lowering of the freezing point and the elevation of the boiling point. These phenomena serve as a basis for molecular weight determinations. If both components of the solution are volatile, each lowers the vapor pressure of the other and the ratios of the two substances in the liquid and vapor phase are not necessarily the same. Use is made of this fact to separate the two substances by distillation.

Equilibrium vapor pressure is the vapor pressure of a system in which two or more phases or a substance coexist in equilibrium. In meteorology, the reference is to water substance, unless otherwise specified. If the system consists of moist air in equilibrium with a plane surface of pure water or ice, the more specialized term *saturation vapor pressure* is usually employed, in which case, the vapor pressure is a function of temperature only. In the atmosphere, the system is complicated by the presence of impurities in liquid or solid water substance (see also **Raoult's Law**), drops or ice crystals or both, existing as aerosols; and, in general, the problem becomes one of nucleation. For example, the difference in vapor pressure over supercooled water drops and ice crystals is the basis for the Bergeron-Findeisen theory of precipitation formation.

VARIABLE (Process). The quantity or characteristic that is the object of measurement in an instrumentation or automatic control system. Other terms used include measurement variable, instrumentation variable, and process variable. The latter term is commonly used in the manufacturing industries. Numerous ways to classify variables have been proposed—by methods of measurement, by end-measurement objectives, and so on. One of the most convenient and meaningful classifications is the physical and/or chemical nature of the variable, as follows:

Thermal Variables. These variables relate to the condition or character of a material dependent upon its thermal energy. Variables included are: *temperature, specific heat, thermal-energy variables* (enthalpy, entropy, etc.), and calorific value.

Radiation Variables. These variables relate to the emission, propagation, and absorption of energy through space or through a material in the form of waves; and by extension, corpuscular emission, propagation, and absorption. Variables included are: *nuclear radiation; electromagnetic radiation* (radiant heat, infrared, visible, and ultraviolet light; x- and cosmic rays; gamma radiation).

Force Variables, including: *total force, moment or torque*, and *force per unit area*, such as pressure, vacuum, and unit stress.

Rate Variables. These variables are concerned with the rate at which a body is moving toward or away from a fixed point. Time always is a component of a rate variable. Variables included are: *flow, speed, velocity*, and *acceleration*.

Quantity Variables. These variables relate to the total quantity of material that exists within specific boundaries. Variables include: *mass* and *weight*.

Physical Property Variables. These variables are concerned with the physical properties of materials with the exception of those properties which are related to chemical composition and direct mass and weight. Variables included are: *density* and *specific gravity, humidity, moisture content, viscosity, consistency*, and *structural characteristics*, such as hardness, ductility, and lattice structure.

Chemical-Composition Variables. These variables relate to the chemical properties and analysis of substances. A very abridged list of analysis variables would include: Identification and concentration of carbon dioxide, carbon monoxide, hydrogen, nitrogen, oxygen, water, hydrogen sulfide, nitrogen oxides, sulfur oxides, methane, ethylene, alcohol, and so on. Also included in this category is measurement of pH (hydrogen ion concentration) and redox measurements. See also **Analysis (Chemical)**.

Electrical Variables. Included here are those variables which are measured as the "product" of a process, as in the case of measuring the current and voltage of a generator, and also as part of an instrumentation system. Numerous transducers, of course, yield electrical signals that represent by inference some other variable quantity, such as a temperature or pressure. Variables in this class include: *electromotive force, electric current, resistance, conductance, inductance, capacitance*, and *impedance*.

Geometric Variables. These variables are related to position or dimension and relate to the fundamental standard of length. Variables include: *position, dimension, contour*, and *level* (as of a material in a tank or bin).

VARIOLITE. A fine-grained basic rock that contains spherulites made up of fibers of feldspar and augite in radial development.

The spherulites themselves are known as varioles, and the texture of such rocks is said to be variolitic.

VARNISH. (1) An organic protective coating similar to paint except that it does not contain colorant. It may be composed of a vegetable oil (linseed), tung, etc.), and solvent or of a synthetic or natural resin and solvent. In the first case the formation of the film is due to polymerization of the oil and in the second to evaporation of the solvent. "Long-oil" varnishes such as spar varnish have a high proportion of drying oil; "short-oil" types have a lower proportion, i.e., furniture varnishes. Spirit varnishes contain such solvents as methanol, toluene, ketones, etc. and often also thinners such as naphtha or other light hydrocarbon.

(2) A hard, tightly adherent deposit on the metal surfaces of automobile engines resulting from resinous oxidation products of gasoline and lubricating oils.

VEGETABLE OILS (Edible). Vegetable oils are prepared from at least ten major oilseeds, plus a few other sources that may develop into high volume at some future date. There are both edible and nonedible vegetable oils. Technical and industrial vegetable oils, such as castorseed and tung oils, are used in nonfood applications. Some oils, such as linseed (flaxseed) and olive oil, depending upon the manner in which they have been treated and refined, find both food and nonfood applications. Other oils, such as soybean, sunflower, rapeseed, sesame, and safflower oils, are used predominantly in food processing and in the production of feedstuffs. Usually, in considering edible vegetable oils, the availability of animal fats, such as butterfat, lard, tallow, etc., and of fish and other marine oils, is noted because there is surprising versatility among all oils and fats, allowing significant substitutions in the same end-product. Perhaps this is best illustrated by the fact that coconut oil, corn (maize) oil, cottonseed oil, palm oil, groundnut (peanut) oil, safflower oil, and soybean oil all are or have been used in commercial margarines for the retail market. The processor of a given brand of margarine will select the oil or a combination of oils, considering price and availability, as well as desirable end-product characteristics (stick or brick; soft tub; diet or imitation; etc.), among other factors. The pressed cakes and meals remaining after extraction of oil from beans and seeds finds wide use in animal feedstuffs.

The consumption of fats and oils by persons in the United States has increased steadily since the early 1960s. In 1963, 46.3 pounds (21 kilograms) were consumed per capita per year, rising to 54.4 pounds (24.7 kilograms) in the late 1970s. During this period, butter dropped from 13.9% of total fats and oils to 7.7%; lard dropped from 12.9% to 4%; margarine increased from 19.4% to 20.2%; shortenings of various kinds increased from 27.2% to 30.6%; and salad and cooking oils increased markedly from 26.6% to 37.5%.

On a worldwide basis, as of the early 1980s, the various sources of edible oils, in terms of volume of production, rank as follows: Soybeans, 50.3%; cottonseed, 16.2%; groundnuts (peanuts), 11.4%; sunflower seeds, 7.9%; rapeseed, 6.9%; copra (coconut), 2.9%; flaxseed (linseed), 1.8%; sesame seed, 1.1%; palm kernel, 0.9%; and safflower seed, 0.6%.

Principal edible uses of these oils are found in cooking and salad oils; frying oils; margarine, mayonnaise, and salad dressings; bakery, cake mix, and pie shortenings; and whipped topping and other nondairy products, such as coffee creamers.

Definitions

Some of the common terms used in describing edible oils and fats are:

Saturated—the state in which all available valence bonds of an atom, especially carbon, are attached to other atoms. The straight-chain alkyls (paraffins) are typical saturated compounds. Several fatty acids found in oils and fats are listed in Table 1. Where no double- or triple-bonds are available, such compounds cannot be hydrogenated because there are no places for attaching additional hydrogen atoms.

Monosaturated—the state where one double bond is present in the compound. Under proper conditions of hydrogenation, an additional hydrogen atom can be added, thus resulting in a saturated compound.

Polyunsaturated—the state where two or more double bonds are present in the compound. Again, under proper conditions of hydrogenation, one or more additional hydrogen atoms can be added, thus resulting in a compound that is less unsaturated or that is saturated, depending upon the number of double bonds originally available and the degree of hydrogenation effected.

Hydrogenation—any reaction of hydrogen with an organic compound. In the case of fats and oils, this is the direct addition of hydrogen to double bonds of unsaturated molecules, resulting in a partially or a fully saturated product.

Hydrogenation can be accomplished with gaseous hydrogen under pressure in the presence of a catalyst (nickel, platinum, or palladium). The degree of saturation of an oil or its fatty acid substituents affects its fluidity (melting or softening point), density, refractive index, and general reactivity. Frequently, the degree of hydrogenation of an oil will be determined by measuring its refractive index. Vegetable and fish oils can be hardened or solidified by catalytic hydrogenation. Partial hydrogenation clarifies some oils and makes them odorless. Fatty oils, such as oleic acid, are converted into stearic acid by hydrogenation. Coconut oil, groundnut (peanut) oil, and cottonseed oils can be made to appear, taste, and smell like lard; or they can be made to resemble tallow. Sometimes, hydrogenated oils are referred to as synthetic shortenings. Generally, hydrogenated oils have higher melting points and lower iodine values than the natural, untreated oils.

TABLE 1. CHARACTERISTICS OF VEGETABLE OIL FATTY ACIDS

Principal fatty acid	Formula weight	Number of double bonds	Position of bonds	Number of carbon atoms	Formula
		SATURATED COMPOUNDS			
Caproic	116.09	0	—	6	$C_5H_{11}COOH$
Caprylic	144.21	0	—	8	$C_7H_{15}COOH$
Capric	172.26	0	—	10	$C_9H_{19}COOH$
Lauric	200.31	0	—	12	$C_{11}H_{23}COOH$
Myristic	228.36	0	—	14	$C_{13}H_{27}COOH$
Palmitic	256.42	0	—	16	$C_{15}H_{31}COOH$
Stearic	258.47	0	—	20	$C_{19}H_{39}COOH$
		UNSATURATED COMPOUNDS			
Palmitolenic	254.42	1		16	$C_{15}H_{29}COOH$
Linolenic	278.42	3	cis-9, cis-12, cis-15	18	$C_{17}H_{29}COOH$
Linoleic	180.44	2	cis-9, cis-12	18	$C_{17}H_{31}COOH$
Oleic	282.45	1	cis-9	18	$C_{17}H_{33}COOH$

For many years, hydrogenation was a batch operation, but in recent years, continuous hydrogenation processes have been displacing the batch methods, especially in large-scale facilities. Hydrogenation pressures vary as well as temperatures, but the latter are usually in the 93–135°C range. It is not uncommon to mix two or more oils prior to hydrogenation. Considerably more detail on the hydrogenation process is given in the entry on **Hydrogenation**.

Deodorizing—crude oils tend to have undesirable odors and tastes. These are due to the presence of various volatile components. These are removed by passing steam through the heated oil under diminished pressure.

Winterizing—because of widespread use of refrigeration, salad oils and other end-products prepared from vegetable oils must not become cloudy or solidify at relatively low storage temperatures. Thus, most salad oils differ from cooking oils, in that the latter, if stored under refrigeration, may slowly solidify and be difficult to pour from a container. To prevent cloudiness and solidification at low temperatures, the oils are "winterized." This involves subjecting the oils to low temperatures in stages, during which time crystals of high-melting-point fat are formed. A final low temperature of about 5.5°C is reached in the process, at which temperature the oil is allowed to stand for a considerable time, during which considerable crystallization occurs. Slow cooling and gentle agitation ensure maximum removal of the high-melting-point fats. The crystalline material remaining after filtration is essentially stearine, with traces of wax, gums, and soaps. Improvements in the winterizing process during the past several years have reduced the time required from 3 to 6 days down to about 5 hours. The more recent processes involve solvent extraction and centrifugation.

Iodine Value (or Number)—the percentage of iodine that will be absorbed by a chemically unsaturated substance, such as vegetable oil, in a given time under specified conditions. The iodine value is a measure of degree of unsaturation. Two methods are described in the "Food Chemicals Codex:" the Hanus method and the Wijs method.

Saponification Number—the number of milligrams of potassium hydroxide required to hydrolyze one gram of sample of an ester (glyceride, fat) or mixture. This test is also described in the "Food Chemicals Codex."

Margarines

Regular margarines (by government regulations) contain at least 80% fat. The remaining content is ~16% water and small amounts (about

TABLE 2. CHARACTERISTICS AND PROPERTIES OF MAJOR VEGETABLE OILS

Property	Coconut oil	Cottonseed oil	Groundnut (peanut) oil	Pal oil	Rapeseed oil
Color	White	Pale-yellow or yellowish-brown to dark ruby-red, or black-red.	Yellow to greenish-yellow	Yellow-brown	Brown (raw); yellow (refined)

4%) of skim or nonfat dry milk and salt. There are several unsalted margarines available. Small amounts of emulsifying agents consisting of lecithin and/or monoglycerides and diglycerides are contained in a number of commercially available margarines. The preservatives most commonly used include sodium benzoate, potassium sorbate, calcium disodium EDTA, isopropyl citrate, and citric acid. Most margarines in the United States are fortified with about 15,000 USP units of vitamin A and a few margarines also contain up to 2000 USP units of vitamin D.

Margarines produced in the United States resemble butter in their proximate composition. The great majority of margarines provide more polyunsaturated fatty acids than an equivalent weight of butter. Diet and imitation margarines were introduced about a decade ago and contain less than 80% fat. The fat content of light blends is about 60% and that of diet imitation margarines is about 40%. Lower fat content in these products is compensated for by higher water content.

A survey of some 40 margarines made in the United States in the late 1970s showed that stick margarines made from partially hydrogenated soybean and cottonseed oil were by far the largest category. Stick margarines made from corn (maize) oil and partially hydrogenated corn oil, and from partially hydrogenated soybean oil and liquid cottonseed oil ranked second and third, respectively. The survey showed that margarines with formulations that included liquid cottonseed oil or liquid and/or partially-hardened palm oil usually contained higher amounts of palmitic acid than did other margarines of the same type. The stearic acid content was reasonably constant for most hard and soft margarines. Margarines made with coconut oil were extremely saturated and contained large amounts of lauric and myristic acids.

Properties of Major Edible Vegetable Oils

The major properties of nine of the principal edible vegetable oils are summarized in Table 2. For descriptions of the constituent acids, see also **Arachidic Acid**; **Capric Acid**; **Caproic Acid**; **Lauric Acid**; **Linoleic Acid**; **Linolenic Acid**; **Myristic Acid**; **Oleic Acid**; **Palmitic Acid**; and **Stearic Acid and Stearates**.

Unconventional Sources of Oils and Proteins

Research efforts continue to find new sources of both food and nonfood oils. Some investigators have reported on the prospects of various gourds indigenous to western North America. Such cucurbits are vigorous and highly drought resistant and produce large quantities of foliage and fruit containing seeds rich in protein and oil, with an extensive system of large, fleshy storage roots which contain starch. Varieties studied have included *Cucurbita foetidissima* and *C. digitata*. Also studied have been varieties of hibiscus (okra). As pointed out by the researchers, the non-conventional protein sources as well as oils would be welcome in a time of protein deficits.

Investigators also have described the potential of the *jojoba plant*, a native of the Sonoran desert of Mexico, Arizona, and California. The desert shrub produces seeds about the size of groundnuts (peanuts) which contain a liquid wax, frequently called *jojoba oil*. The oil is similar to

sperm whale oil in its suitability for a number of industrial applications. Sperm whale was placed on the endangered species list by a number of countries, including the United States, in 1971. Prospects of an edible oil from jojoba are undetermined, but the meal remaining after pressing jojoba seeds contains 30–35% protein, and may have potential as a livestock feed. A new jojoba industry would mean a new, renewable resource that has not been exploited before and would offer economic relief to the people of the Sonoran desert region. Other researchers have recently shown a renewed interest in the lupine as a source of edible oils and proteins.

VESUVIANITE. The mineral vesuvianite is a very complex silicate of calcium and aluminum with fluorine which may also contain varying amounts of boron, iron, lithium, magnesium, manganese, potassium, sodium and titanium. A suggested formula is $Ca_{10}Mg_2Al_4(SiO_4)_5(Si_2O_7)_2(OH)_4$. Its tetragonal crystals are usually short, somewhat stoutish prisms, sometimes pyramids, but columnar to massive varieties are common. It is essentially without cleavage; fracture, uneven; brittle hardness, 6–7; specific gravity, 3.3–3.5; luster, vitreous to greasy resinous; color, commonly some shade of brown, green, or white, may be reddish, bluish or yellowish; may be transparent, but is usually translucent.

This mineral was formerly called idocrase, having been named Haüy from the Greek words meaning *form* and *mixture* because it resembled crystals of other species, scarcely a valid distinction. Werner gave it the name vesuvianite from Mt. Vesuvius where it was first found blocks of limestone appearing as inclusions in the lava. Vesuvianite not a constituent of the igneous rocks, but rather a contact metamorphic mineral resulting from the alteration of impure limestones and dolomites It is usually associated with diopside, wollastonite, epidote, grossularite and garnet. There are many localities worthy of mention among which are: The Urals, Central Europe, Rumania, Trentino and Monzoni in Italy, as well as at Mt. Vesuvius and Mt. Somma, Switzerland, Mexico and Japan. In the United States vesuvianite is found in Androscoggin and York Counties in Maine; Orange and Warren Counties, New York; Sussex County, New Jersey; Garland County, Arkansas; and Riverside and Tulare Counties in California.

VINEGAR. Vinegar is the liquid condiment or food flavoring used to give a sharp or sour taste to foods. It is also used as a preservative in pickling and as the sour component in many different sauces, dressings, and gravies.

Vinegar results from the action of the enzymes of bacteria of the genus *Acetobacter* and some others on dilute solutions of ethyl alcohol such as cider, wine, beer, or diluted distilled alcohol. See also **Ethyl Alcohol**. Most vinegars for table use, e.g., in the dressing of salads, derive from the acetic acid–bacterial fermentation of wine or cider. See also **Acetic Acid**. These latter, in turn, are produced by alcoholic fermentation (see also **Fermentation**) of dilute sugar solutions such as grape juice, apple juice, or malt. *Saccharomyces cerevisiae* is the yeast involved most frequently in alcoholic fermentation, i.e., in the enzymatic conversion of fermentable sugars to dilute alcoholic solutions. See also **Yeasts and Molds**. Although fruits and honey are used most frequently as sources of fermentable sugar for vinegar production, barley malt and, in the Orient, rice, after hydrolysis of starch, serve as primary sources. See also **Food Processing**.

Some raw materials used for vinegar production are listed in Table 1.

A number of factors govern the composition of vinegar: the nature of the raw material, the substances added to promote alcoholic fermentation and the growth and activity of *Acetobacter*, the procedure used for the acetification, and finally the aging, stabilization, and bottling operations.

Manufacture

Only since the mid-1800s has it been known that yeast and bacteria are the cause of fermentation and vinegar formation.

TABLE 1. RAW MATERIALS USED TO MAKE VINEGAR

Raw material
MAINLY SUGARY
jujube
sweet potato
dates
citrus
persimmon
pear
sugar cane
plum
tomato
kiwi fruit
pineapple

honey
palm sap
muscavado (brown sugar)
MAINLY STARCHY
potato, corn flour
soyabean
seaweed
rice
grain starch
VARIOUS
onions
bamboo grass
wood
whey
coconut water
vinasse (distillation residue)

Starch Hydrolysis and Alcoholic Fermentation. In general, because yeasts cannot utilize starch directly as a carbon source, the starch must first be hydrolyzed to sugar. Malt vinegars are made from malted barley or a mixture of malted barley with other starchy grains. Malt enzymes convert starch to sugars readily fermentable by *Saccharomyces* yeasts. In Japan, where vinegars are made from rice, a mixture of hydrolyzing enzymes produced by the fungus *Aspergillus oryzae* converts rice starches to sugars. Alcoholic fermentation is frequently conducted in two phases, although in a modern vinegar plant it can be conducted in one. The first phase is a vigorous fermentation during which the rapid evolution of carbon dioxide protects the alcoholic solution from air. The second or slower phase is fermentation of the residual sugar at a lower rate, during which, again, protection from air is required. In the first phase, 50–100 mg SO_2/L of sugarcontaining mash is added, followed after approximately 1 h by 1–3% of an actively fermenting, pure-culture starter of *Saccharomyces cerevisiae*. The fermentation process is monitored for disappearance of sugar and increase in temperature. Rates of alcoholic fermentation are highest at ca 25–30°C; higher temperatures tend to damage enzyme systems.

Both the fermentation of hexose sugars to ethanol and carbon dioxide and the oxidation of ethanol to acetic acid are exothermic (heat yielding) processes (see **Sugar**). Depending on the size of the fermenter and the rates of fermentation and aeration, loss of waste heat is apportioned among radiation, conduction, and vaporization of water and ethanol plus carbon dioxide. Although small fermenters may require no cooling, large ones require more cooling than occurs through natural radiation and conductance.

Acetic Acid. Ethyl alcohol is converted to acetic acid by air oxidation catalyzed by the enzymes within bacteria of the genus *Acetobacter*:

$$46\ \text{g}\ C_2H_5OH + 32\ \text{g}\ O_2 \longrightarrow 60\ \text{g}\ CH_3COOH + 18\ \text{g}\ H_2O + 487.2\ \text{kJ}(116.4\ \text{kcal})$$

One gram of ethanol should yield 1.304 g acetic acid. Practical yields are 77–85%. In contrast with the well-known Embden-Meyerhof-Parnass glycolysis pathway for the conversion of hexose sugars to alcohol, the steps in conversion of ethanol to acetic acid remain in some doubt.

Orleans Process. In the Orleans process, wine oxidizes slowly in a barrel where it is covered with a film of *Acetobacter*. Holes that are covered with screens to exclude insects are bored in each barrel head to permit

access to air. Wine is added through the bung hole with a long-stemmed funnel below the surface of the bacterial film and without disturbing the film. Wines with 10–12% ethanol give vinegars of 8–10% acetic acid concentration. Orleans vinegars are characterized by a relatively high concentration of ethyl acetate, detected by its pleasantly strong fruity odor.

Modena-Style or Balsamic Vinegar Process. Balsamic vinegars are made in and around the city of Modena in central Italy and consist of two general types. The traditional product is made from juice of the Trebbiano grape concentrated to about 40% sugar by direct flame heating of the container. *Zygosaccharomyces, Saccharomyces cerevisiae*, and *Gluconobacter* in barrels convert the sugars to ethyl alcohol and gluconic acid as principal products. The ethyl alcohol is converted to acetic acid by the *Acetobacter* and *Gluconobacter*. Subsequent reactions form many taste and odor substances, among which the ester ethyl acetate is of key importance. Years of age in barrels result in a condiment having a harmonious balance of sweetness and tartness. Aceto Balsamico di Modena differs from the Tradizionale in that it is a blend of ordinary wine vinegar with concentrate. Lacking the complex character of Tradizionale and being younger, it is much less expensive.

Generator Process. Generators are packed with shavings of beech wood, which tend to curl and thus provide packing that does not consolidate but allows open spaces for the free flow of liquid and air. Beech wood does not contribute undesirable flavors or impurities to the vinegar. In the modern generator, a recirculating pump transfers the partially acetified alcoholic mixture from the bottom section of the generator to a distributing system at the top of the packed section. Cooling coils may be located in the packed section, but more frequently are placed at the bottom of the receiver section or are incorporated in the line for recirculating the liquid.

Various species and many strains of *Acetobacter* are used in vinegar production. Aeration rates, optimum temperatures and nutrient requirements vary with individual strains. In general, fermentation alcohol substrates require minimal nutrient supplementation while their addition is necessary for distilled alcohol substrates.

Adaptation of the surface-film growth procedure for producing antibiotics to an aerated submerged-culture process has been successful in making vinegar.

The most widely used submerged-culture oxidizer is the Frings acetator. It uses a bottom-driven hollow rotor turning in a field of stationary vanes arranged in such a way that the air which is drawn in is intimately mixed with the liquid throughout the whole bottom area of the tank.

Submerged-culture oxidizers are usually operated on a semicontinuous basis. In most cases, ca half the liquid in the tank is removed every 1–2 d, when the alcohol concentration has dropped to 0.1–0.2 vol %. The removed vinegar is replaced with wine or mash of richer ethanol and lower acetic acid concentration, giving a mixture in the tank of 5–6 vol % ethanol and 6–8 vol % of acetic acid. These are the optimum conditions for *Acetobacter* growth.

Foam production is most troublesome under conditions adverse to bacterial growth and thus can be minimized by keeping nutrient, ethanol, and acetic acid concentrations in the optimum ranges (see **Defoaming Agents**). Temperature and aeration rate are also critical.

Submerged culture oxidizers can also be operated on a continuous basis. Optimum production, however, is achieved by semicontinuous operation because the composition of vinegar desired in the withdrawal stream is so low in ethanol that vigorous bacterial growth is impeded. Bacterial concentrations up to 100×10^6cells/cm^3 have been reported in generators making about 20% vinegars.

Fluidized-Bed Vinegar Reactors. Intimate contact of air with *Acetobacter* cells is achieved in fluidized-bed or tower-type systems. Air introduced through perforations in the bottom of each unit suspends the mixture of liquid and microorganisms within the unit. Air bubbles penetrating the bottom plate keep *Acetobacter* in suspension and active for the ethanol oxidation in the liquid phase.

Vinegars with High Concentrations of Acetic Acid. The U.S. regulations require at least 4 g acetic acid/100 cm^3 vinegar. Commercial vinegar and many quality table vinegars are significantly more concentrated. Submerged-culture oxidizers easily give acetic acid concentrations of 10–13 g/cm^3. Submerged-culture oxidizer techniques that produce vinegars with acetic acid concentrations ranging from 15–20% are now in commercial use. Continuous aeration, careful stepwise addition of ethanol as it is oxidized and careful control of temperature seem to be the keys to successful operation.

Vinegar Eels and Mother of Vinegar. Although esthetically undesirable, nematodes, known as vinegar eels, may actually be of some assistance in consuming dead bacteria from the surface of the packing material in the vinegar tank, and thus may aid in prolonging the operation of the system. Vinegar eels are removed from the raw vinegar by filtration and pasteurization before the vinegar is sold or used further in pickling or other processes.

Processing

Raw vinegars vary widely in stability and may contain materials that form cloudiness or deposits. Vinegars that carry a high and cloud suspension of bacterial cells are clarified and stabilized with bentonite and similar agents or activated carbon. Membrane filtration can be combined with aseptic bottling to provide a product free of all microorganisms. Wine, cider, and malt vinegars benefit from aging, which improves the character of the product. Vinegars bottled for table use and pickling usually are pasteurized at 77–78°C.

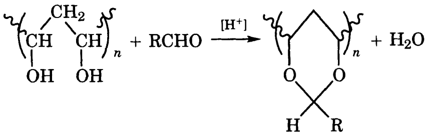
VINYL ACETAL POLYMERS. Vinyl acetal polymers are made by the acid-catalyzed acetalization of poly(vinyl alcohol) with aldehydes.



Although many members of this class of resins have been made, only poly(vinyl formal) (PVF) and poly(vinyl butyral) (PVB) are made in significant commercial quantities.

Synthesis and Structure

Poly(vinyl acetals) are made from poly(vinyl alcohol) and aldehydes by acid-catalyzed addition–dehydration. The degree of acetalization and the conditions used during the reaction significantly affect product properties. Batch and continuous processes in both aqueous and organic media are used during manufacturing. In single-stage batch processes, hydrolysis of poly(vinyl acetate) and acetalization of the poly(vinyl alcohol) hydrolysis product are carried out in the same kettle at the same time. In two-stage batch processes, hydrolysis and acetalization take place in separate kettles.

Physical Properties

Unformulated poly(vinyl acetal) resins form hard, unpliable materials which are difficult to process without using solvents or plasticizers. Plasticizers aid resin processing, lower the glass-transition temperature, T_g, and can profoundly change other physical properties of the resins.

Poly(vinyl acetal)s can be formulated with other thermoplastic resins and with a variety of multifunctional cross-linkers. When cross-linking takes place the resin becomes thermoset. Thermosetting generally increases thermal stability, rigidity, and abrasion resistance, and improves resistance to solvents and to acids and bases. It also severely limits processibility by making the resin insoluble and impossible to extrude.

Health and Safety Factors

Representative unformulated PVB and PVF resins are practically nontoxic orally (rats) and no more than slightly toxic after skin application (rabbits).

Some forms of these products may contain sufficient fines to be considered nuisance dust and present dust explosion potential if sufficient quantities are dispersed in air. Unformulated PVB and PVF resins have flash points above 370°C. The lower explosive limit (lel) for PVB dust in air is about 20 g/m^2.

TABLE 1. PHYSICAL PROPERTIES OF BUTVAR RESINS

[e] B-72 in 7.5 wt % anhydrous methanol at 20°C; B-76 and B-79 in 5.0 wt % SD 29 ethanol at 25°C; B-74, B-90, and B-98 in 6.0 wt % anhydrous methanol at 20°C, all using an Ostwald-Cannon-Fenske viscometer.

Poly(vinyl butyral)

Several grades are available that differ primarily in residual vinyl alcohol content and molecular weight. Both variables strongly affect solution viscosity, melt flow characteristics, and other physical properties. Some physical, properties of various grades of Monsanto's Butvar resins are listed in Table 1. In general, resin melt and solution viscosity increase with increasing molecular weight and vinyl alcohol content, whereas the tensile strength of materials made from PVB increases with vinyl alcohol content for a given molecular weight.

Commercially available PVB resins are generally soluble in lower molecular weight alcohols, glycol ethers, and certain mixtures of polar and nonpolar solvents. A common solvent for all of the Butvar resins is a combination of 60 parts of toluene and 40 parts of ethanol (95%) by weight.

PVB resins are also compatible with a limited number of plasticizers and resins. Plasticizers improve processibility, lower T_g, and increase flexibility and resiliency over a broad temperature range.

PVB combinations with the thermoplastic resins nitrocellulose or shellac have been used as sealers for wood finishing. In these applications the PVB component adds flexibility and adhesion. Tough, optically clear blends have been made with aliphatic polyurethanes. Thermosets are prepared with cross-linkers that form covalent bonds with hydroxyl groups.

Manufacture. PVBs are manufactured by a variety of two-stage heterogeneous processes. In one of these an alcohol solution of poly(vinyl acetate) and an acid catalyst are heated to 60–80°C with strong agitation. As the poly(vinyl alcohol) forms, it precipitates from solution. As the reaction approaches completion the reactants go into solution. When the reaction is complete, the catalyst is neutralized and the PVB is precipitated from solution with water, washed, and centrifuged and dried. Resin from this process has very low residual vinyl acetate and very low levels of gel from intermolecular acetalization.

In the second stage of a representative aqueous process, an aqueous solution of poly(vinyl alcohol) is heated with butyraldehyde and an acid catalyst. PVB precipitates from solution as it forms. Because PVB resin precipitates early in the reaction there is a tendency toward high levels of intermolecular acetalization. Cross-linking can be minimized by adding emulsifiers to control particle size or substances like ammonium thiocyanate or urea to improve the solubility of PVB in the aqueous phase.

Applications. During 1994, about 68,000 t of unplasticized PVB was manufactured worldwide. Of this, the overwhelming majority, about 66,000 t, was plasticized and extruded into sheet for use in laminated safety glass. Only about 2,300 t of unplasticized PVB was used for noninterlayer applications.

Plasticized PVB is uniquely suited for safety and security glazing applications. It is easily extruded into sheet. The laminated sheet exhibits high adhesion to glass, optical clarity, stability to sunlight, and high tear strength and impact-absorbing characteristics, all of which are demanded for safety glazing use.

Most laminated safety glazings are glass-PVB-glass trilayer composites. Adhesion of plasticized PVB to clean glass is very high.

Some categories of nonglazing uses for PVB are as follows: phenolic/adhesives; metal/glass binders; hard copy printing; and coatings/additives.

Poly(vinyl formal)

Estimated worldwide production of poly(vinyl formal) resin was about 2700 t in 1994. PVF resins are currently manufactured by Wacker Chemie (Pioloform F) in Germany and by Chisso (Vinylec) in Japan. Poly(vinyl formal) resins are free-flowing white powders with a poly(vinyl formal) content of about 81 wt %. Chemical resistance of poly(vinyl formal) to acids, bases, and aliphatic hydrocarbons is excellent, and chemical resistance to alcohols, aromatic hydrocarbons, esters, and ketones is good; however, chemical resistance to chlorinated solvents is rated poor. In general, PVF resins are soluble in a limited number of solvents and in certain mixtures of alcohols and aromatic hydrocarbons. The solubility of PVF resins in polar solvents increases with increasing proportions of residual vinyl acetate content. Increasing vinyl acetate content also reduces resin stiffness and tensile and impact strength. Solution viscosity increases with increasing vinyl alcohol content and with the average molecular weight of the resin.

PVF resins are generally compatible with phthalate, phosphate, adipate, and dibenzoate plasticizers, and with phenolic, melamine–formaldehyde, urea–formaldehyde, unsaturated polyester, epoxy, polyurethane, and cellulose acetate butylate resins. They are incompatible with polyamide, ethyl cellulose, and poly(vinyl chloride) resins.

Commercial PVF is manufactured by a single-stage batch process in acetic acid. The ratio of vinyl acetate and vinyl alcohol components in the acetal product is controlled by the ratio of acetic acid, water, and formaldehyde used.

Applications. PVF resins are used almost exclusively to make electric and magnetic wire insulation. In these applications the PVF resin component helps provide toughness, as well as abrasion and thermal resistance.

PVF resins have also been used in a variety of other applications, including conductive films, electrophotographic binders, as a component for inks and in membranes, photoimaging, solder masks, and reprographic toners.

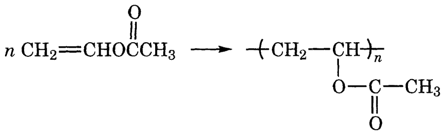
VINYL ACETATE POLYMERS. Vinyl acetate is a colorless, flammable liquid having an initially pleasant odor which quickly becomes sharp and irritating. Table 1 lists the physical properties of the monomer.

The most important chemical reaction of vinyl acetate is free-radical polymerization. The reaction is summarized as follows:



Vinyl acetate has been polymerized by bulk, suspension, solution, and emulsion methods. It copolymerizes readily with some monomers but not with others.

TABLE 1. SOME PROPERTIES AND CHARACTERISTICS OF VINYL ACETATE

Property	Value
formula weight	86.09
physical state	liquid
flammable limits in air (101.3 kPa[a]), vol %	LEL 2.6, UEL 13.4
flash point,°C	
Tag closed cup (ASTM D56)	−8
Tag open cup (ASTM D1310)	−4
autoignition temperature,°C	426.9
bp at 101.3 kpa[a],°C	72.7
relative evaporation rate (n − butyl acetate = 1)	8.9
vapor pressure at 20°C, kPa[a]	11.8
critical temp,°C	246
critical pressure, kPa[b]	3950
color	clear and colorless
sp gr, 20/20°C	0.934
vapor density (air = 1.00)	2.97
viscosity at 20°C	0.43 cps
fp,°C	−92.8
heat of combustion at 25°C	−495.0 kcal/mol
heat of vaporization (1 atm)	87.6 cal/g
heat of formation (liquid at 25°C), kJ/mol[c]	−349.4
heat of polarization, kJ/mol[c]	89.1
specific heat at 20°C (liquid)	0.46 cal/g°C
odor	sweetish smell in small quantities
reactivity	reactive with self and variety of other chemicals; stable when properly stored and inhibited
light sensitivity	light promotes polymerization
electrical conductivity at 23°C	2.6 × 104 pS/m(1 S = 1 mho)
refractive index, n_D^{20}	1.3953
surface tension at 20°C, mN/m(= dyn/cm)	23.6
coefficient of cubical expansion	0.00137/°C at 20°C

[a] To convert kPa to mm Hg, multiply by 7.5.
[b] To convert kPa to atm, divide by 101.3.
[c] To convert kJ/mol to kcal/mol, divide by 4.184.

Hydrolysis of vinyl acetate is catalyzed by acidic and basic catalysts to form acetic acid and vinyl alcohol which rapidly tautomerizes to acetaldehyde. This rate of hydrolysis of vinyl acetate is 1000 times that of its saturated analogue, ethyl acetate, in alkaline media. Other chemical reactions which vinyl acetate may undergo are addition across the double bond, transesterification to other vinyl esters, and oxidation.

Vinyl acetate monomer is supplied in three grades, which differ in the amount of inhibitor they contain but otherwise have identical specifications. In storage vinyl acetate should be kept away from ignition sources. It should be stored in a cool environment away from heat, direct sunlight, oxidizing materials, and free-radical generating chemicals to avoid rapid uncontrolled polymerization. Bulk storage should be blanketed with dry nitrogen.

Health and Safety Aspects

NIOSH recommends a ceiling limit of 4 ppm for 15 minutes of exposure to vinyl acetate vapor. The ACGIH recommends an 8-hour TLV Time Weighted Average of 10 ppm and a 15 minute short-term exposure limit of 15 ppm to its vapor. Vinyl acetate is a severe eye and skin irritant, forming blisters on the skin, and redness, swelling, or corneal burns on the eyes. The vapor is irritating to the nose and throat, and high levels of exposure may result in pulmonary edema. Vinyl acetate has moderate acute toxicity if ingested.

Vinyl Acetate Polymers

Properties. Poly(vinyl acetate) (PVAc) polymer resins are manufactured in a variety of molecular weights. Some physical properties of the polymer are listed in Table 2. With increasing molecular weight, properties vary from viscous liquids to low melting solids to tough, horny materials. They are neutral, water-white to stray-colored, tasteless, odorless, and nontoxic. The resins have no sharply defined melting points but become softer with increasing temperature. Due to their solubility parameter, they are soluble in organic solvents, but are insoluble in the lower alcohols (excluding methanol), glycols, water, and nonpolar liquids.

TABLE 2. PHYSICAL CONSTANTS FOR POLY(VINYL ACETATE)

Property	Value
absorption of water at 20°C for 24–144 h, %	3–6
coefficient of thermal expansion, K^{-1}	
cubic	6.7×10^{-4}
linear, below T_g	7×10^{-5}
above T_g	22×10^{-5}
compressibility, $cm^3/(g{\cdot}kPa)$[a]	17.8×10^{-6}
decomposition temperature,°C	150
density at 20°C, g/cm^3	1.191
dielectric constant at 50°C, at 2 MHz	3.5
dielectric dissipation factor at 50°C, at 2 MHz, tan δ	150
dielectric strength at 30°C, V/L	0.394
dipole moment at 20°C, C·m[b] per monomer unit	2.30
elongation at break, at 20°C and 0% rh, %	10–20
glass-transition temperature, T_g, °C	28–31
pressure dependence,°C/100 MPa[c]	0.22

[c] To convert MPa to psi, multiply by 145; GPa to psi, multiply by 145,000.
[d] To convert J to cal, divide by 4.184.
[e] To convert J/m to lbf/in., divide by 53.38.

The chemical properties of PVAc are those of an aliphatic ester. Thus, acidic or basic hydrolysis produces poly(vinyl alcohol) and acetic acid or the acetate of the basic cation.

Poly(vinyl acetate) emulsion films adhere well to most surfaces that have relatively high surface energy, (e.g., wood, paper, glass, and metal), and have good binding capacity for pigments and fillers. PVAc film can be laid down on a damp surface with trapped moisture gradually passing through the film without lifting or blistering it. Poly(vinyl acetate) polymers are environmentally friendly because they easily biodegrade.

Polymerization Processes. Vinyl acetate has been polymerized industrially by bulk, solution, suspension, and emulsion processes. Perhaps 90% of the material identified as poly(vinyl acetate) or copolymers that are predominantly vinyl acetate are made by emulsion techniques.

Emulsion Polymerization. Poly(vinyl acetate)-based emulsion polymers are produced by the polymerization of an emulsified monomer through free-radicals generated by an initiator system. An emulsion recipe, in general, contains monomer, water, protective colloid or surfactant, initiator, buffer, and perhaps a molecular weight regulator.

Many different combinations of surfactant and protective colloid are used in emulsion polymerizations of vinyl acetate as stabilizers.

The properties of the emulsion and the polymeric film depend to a large extent on the identity and quantity of the stabilizers. Poly(vinyl acetate) emulsions can be made with a surfactant alone or with a protective colloid alone, but the usual practice is to use a combination of the two. In general, the greater the quantity of stabilizers in a recipe, the smaller the particle size of the emulsion.

The initiators used in vinyl acetate polymerizations are the familiar free-radical types. Buffers are frequently added to emulsion recipes. Vinyl acetate emulsion polymerization recipes are usually buffered to pH 4–5. The pH of most commercially available emulsions is 4–6.

A chain-transfer agent is added to vinyl acetate polymerizations to control the polymer molecular weight.

A polymerization process may consist of simply charging all ingredients to the reactor, heating to reflux, and stirring until the reaction is over while controlling the heat removal at the reaction temperature using cooling systems. However, this simple procedure is seldom followed.

Industrially, polymerizations are carried out to over 99% conversion and thus there is no need to reduce the unreacted monomer unless very low levels are required to meet regulatory, product, or workplace requirements. Most poly(vinyl acetate) emulsions contain less than 0.5 wt % unreacted vinyl acetate. All of the processes are operated in conventional glass-lined or stainless steel kettles or reactors. Control of the process is important to ensure reproducibility of the product.

Bulk Polymerizations. In the bulk polymerization of vinyl acetate the viscosity increases significantly as the polymer forms making it difficult to remove heat from the process. Low molecular weight polymers have been made in this fashion. Continuous processes are known to be used for bulk polymerizations.

Suspension Polymerization. The suspension or pearl polymerization process has been used to prepare polymers for adhesive and coating applications and for conversion to poly(vinyl alcohol). Suspension polymerization are carried out with monomer-soluble initiators predominantly, with low levels of stabilizers. Continuous tubular polymerization of vinyl acetate in suspension yields stable dispersions of beads with narrow particle size distributions at high yields.

Solution Polymerization. Solution polymerization of vinyl acetate is carried out mainly as an intermediate step to the manufacture of poly(vinyl alcohol). A small amount of solution-polymerized vinyl acetate is prepared for the merchant market. When solution polymerization is carried out, the solvent acts as a chain-transfer agent, and depending on its transfer constant, has an effect on the molecular weight of the product. Continuous solution polymers of poly(vinyl acetate) in tubular reactors have been prepared at high yield and throughput.

Propagation. The rate of emulsion polymerization has been found to depend on initiator, monomer, and emulsifier concentrations. Vinyl acetate polymerizes chiefly in the usual head-to-tail fashion, but some of the monomers orient head-to-head and tail-to-tail as the chain grows. In vinyl acetate polymerizations, the molecular weights of the products increase with the extent of conversion: the ratio of weight-to-number-average-degree-of-polymerization also changes, becoming larger at higher conversions.

Chain Transfer. At the molecular scale, vinyl acetate polymerizations generally are understood as free-radical polymerizations, but are characterized in particular by a relatively large amount of chain transfer.

Grafting and Stabilizers. The degree of grafting of poly(vinyl acetate) (PVAc) on poly(vinyl alcohol) (PVA) and other stabilizers during emulsion polymerization strongly affects latex properties such as viscosity, rheology, and polymer solubility.

Copolymers. Vinyl acetate copolymerizes easily with a few monomers, e.g., ethylene, vinyl chloride, and vinyl neodecanoate, which have reactivity ratios close to its own. Block copolymers of vinyl acetate with methyl methacrylate, acrylic acid, acrylonitrile, and vinyl pyrrolidinone have been prepared by copolymerization in viscous conditions, with solvents that are poor solvents for the vinyl acetate macroradical.

Blends. Latex film properties are commonly modified through the blending of latexes, e.g., a "soft" polymer is made slightly harder by blending with a "hard" latex.

Specifications and Standards. Borax stability is an important property in adhesives, paper, and textile applications. Other emulsion properties tabulated by manufacturers include tolerance to specific solvents, surface tension, minimum film-forming temperature, dilution stability, freeze–thaw stability, percent soluble polymer, and molecular weight.

Poly(vinyl acetate) and its copolymers with ethylene are available as spray-dried emulsion solids with average particle sizes of 2–20 μm; the product can be reconstituted to an emulsion by addition of water or it can be added directly to formulations, e.g., concrete.

Uses. The uses of poly(vinyl acetate) adhesive are packaging and wood gluing. PVAc copolymer adhesives are finding application in more diverse areas such as construction and adhesion to more difficult to bond surfaces because of the range of adhesion and the flexibility that may be built into the polymer.

Poly(vinyl acetate) emulsions can be used in high speed gluing equipment. Poly(vinyl acetate) homopolymers adhere well to porous or cellulosic surfaces, e.g., wood, paper, cloth, leather, and ceramics. Homopolymer films tend to creep less than copolymer or terpolymer films. They are especially suitable in adhesives for high speed packaging operations.

Poly(vinyl acetate) dry resins and ethylene–vinyl acetate (EVA) copolymers are used in solvent adhesives, which can be applied by total industrial techniques, e.g., brushing, knife-coating, roller-coating, spraying, or dipping.

Paints prepared from poly(vinyl acetate) and its copolymers form flexible, durable films with good adhesion to clean surfaces, including wood, plaster, concrete, stone, brick, cinder blocks, asbestos board, asphalt, tar paper, wallboards, aluminum, and galvanized iron.

Poly(vinyl acetate) emulsions and resins have been used as the binder in coatings for paper and paperboard since 1955. The coatings may be clear, colored, or pigmented, and are glossy, odorless, tasteless, grease-proof, nonyellowing, and heat-sealable. Conventional paper-coating equipment is used.

The use of vinyl acetate copolymers as binding agents for nonwoven fabrics has grown rapidly. Poly(vinyl acetate) was first used in concrete in the 1940s as a thermoplastic polymer to strengthen the concrete matrix. Vinyl acetate resins are useful as antishrinking agents for glass fiber-reinforced polyester molding resins and as binders for numerous materials. Emulsions containing added poly(vinyl alcohol) and dichromate are used to make light-sensitive stencil screens for textile printing and ceramic decoration. Vinyl acetate polymers have long been used as chewing gum bases.

VINYL ALCOHOL POLYMERS. Poly(vinyl alcohol) (PVA), a polyhydroxy polymer, is the largest-volume synthetic, water-soluble resin produced in the world. It is commercially manufactured by the hydrolysis of poly(vinyl acetate), because monomeric vinyl alcohol cannot be obtained in quantities and purity that makes polymerization to poly(vinyl alcohol) feasible.

The main uses of PVA are in textile sizing, adhesives, protective colloids for emulsion polymerization, fibers, production of poly(vinyl butyral), and paper sizing. Significant volumes are also used in the production of concrete additives and joint cements for building construction and water-soluble films for containment bags for hospital laundry, pesticides, herbicides, and fertilizers. Smaller volumes are consumed as emulsifiers for cosmetics, temporary protective film coatings, soil binding to control erosion, and photoprinting plates.

Physical Properties

The physical properties of poly(vinyl alcohol) are highly correlated with the method of preparation. The final properties are affected by the polymerization conditions of the parent poly(vinyl acetate), the hydrolysis conditions, drying, and grinding. Further, the term poly(vinyl alcohol) refers to an array of products that can be considered copolymers of vinyl acetate and vinyl alcohol. Representative properties are shown in Table 1.

The ability of PVA to crystallize is the single most important physical property of PVA as it controls water solubility, water sensitivity, tensile strength, oxygen barrier properties, and thermoplastic properties.

The glass-transition temperature, T_g, of fully hydrolyzed PVA has been determined to be 85°C for high molecular weight material. Poly(vinyl alcohol) is only soluble in highly polar solvents, such as water, dimethyl sulfoxide, acetamide, glycols, and dimethylformamide. The solubility in water is a function of degree of polymerization (DP) and hydrolysis.

TABLE 1. PHYSICAL PROPERTIES OF POLY(VINYL ALCOHOL)

Property	Value

specific gravity	1.27–1.31
tensile strength, MPa[a]	67–110[b]
elongation, %	0–300
specific heat, J/(g · K)[c]	1.67
thermal conductivity, W/(m·K)	0.2
T_g, K	358[b]
mp, K	503[b]
electrical resistivity, Ω · cm	(3.1–3.8) × 10^7
refractive index, n_D^{20}	1.55
degree of crystallinity	0–0.54
storage stability (solid)	indefinite when protected from moisture
flammability	similar to paper
stability in sunlight	excellent

[a] To convert MPa to psi, multiply by 145.
[b] 98–99% hydrolyzed.
[c] To convert J to cal, divide by 4.184.

The viscosities of PVA solutions are mainly dependent on molecular weight and solution concentration. The viscosity increases with increasing degree of hydrolysis and decreases with increasing temperature.

The tensile strength of unplasticized PVA depends on degree of hydrolysis, molecular weight, and relative humidity. Tensile elongation of PVA is extremely sensitive to humidity and ranges from <10% when completely dry to 300–400% at 80% rh. Addition of plasticizer can double these values. Poly(vinyl alcohol) is virtually unaffected by hydrocarbons, chlorinated hydrocarbons, carboxylic acid esters, greases, and animal or vegetable oils. Resistance to organic solvents increases with increasing hydrolysis.

The oxygen-barrier properties of PVA at low humidity are the best of any synthetic resin. However, barrier performance deteriorates above 60% rh.

The surface tension of aqueous solutions of PVA varies with concentration, temperature, degree of hydrolysis, and acetate distribution on the PVA backbone. Surface tension decreases slightly as the molecular weight is reduced. The relationship between the intrinsic viscosity and molecular weight changes with degree of hydrolysis of the polymer.

Chemical Properties

Poly(vinyl alcohol) participates in chemical reactions in a manner similar to other secondary polyhydric alcohols. Of greatest commercial importance are reactions with aldehydes to form acetals, such as poly(vinyl butyral) and poly(vinyl formal).

Boric acid and borax form cyclic esters with poly(vinyl alcohol).

An unlimited number of organic esters can be prepared by reactions of poly(vinyl alcohol) employing standard synthesis. Ethers of poly(vinyl alcohol) are easily formed. Insoluble internal ethers are formed by the elimination of water, a reaction catalyzed by mineral acids and alkali.

Poly(vinyl alcohol) and aldehydes form products which find use in the manufacture of safety glass and as adhesives for hydrophilic surfaces.

Poly(vinyl alcohol) can be readily cross-linked using a multifunctional compound that reacts with hydroxyl groups. These types of reactions are of significant industrial importance as they provide ways to obtain improved water resistance of the poly(vinyl alcohol) or to increase the viscosity rapidly. The thermal decomposition of poly(vinyl alcohol) in the absence of oxygen occurs in two stages. The first stage begins at about 200°C and is mainly dehydration, accompanied by the formation of volatile products. Further heating to 400–500°C yields carbon and hydrocarbons.

Poly(vinyl alcohol) is one of the few truly biodegradable synthetic polymers; the degradation products are water and carbon dioxide. At least 55 species or varieties of microorganisms have been shown to degrade or participate in the degradation of PVA.

Manufacture

Poly(vinyl alcohol) can be derived from the hydrolysis of a variety of poly(vinyl esters), such as poly(vinyl acetate), poly(vinyl formate), and poly(vinyl benzoate), and of poly(vinyl ethers). However, all commercially produced poly(vinyl alcohol) is manufactured by the hydrolysis of poly(vinyl acetate). The manufacturing process can be viewed as one segment that deals with the polymerization of vinyl acetate and another that handles the hydrolysis of poly(vinyl acetate) to poly(vinyl alcohol).

Vinyl acetate is polymerized commercially using free-radical polymerization in either methanol or, in some circumstances, ethanol.

Poly(vinyl acetate) can be converted to poly(vinyl alcohol) by transesterification, hydrolysis, or aminolysis. Industrially, the most important reaction is that of transesterification, where a small amount of acid or base is added in catalytic amounts to promote the ester exchange.

Copolymers

Numerous vinyl alcohol copolymers have been prepared. Copolymers with ethylene and methacrylate are the only copolymers that have found sizable commercial utility. Ethylene–vinyl alcohol (EVOH) copolymers containing 20–30 mol % ethylene are used as an oxygen barrier in food packaging. Vinyl alcohol–methyl methacrylate copolymers are used as sizing agents in the textile industry. The presence of the methacrylate unit disrupts the crystallinity, making the product easier to remove during the desizing operation. The product is especially useful as an alkaline-resistant textile size.

Processing

Poly(vinyl alcohol) is not considered a thermoplastic polymer because the degradation temperature is below that of the melting point. Thus, industrial applications of poly(vinyl alcohol) are based on and limited by the use of water solutions.

Specifications and Standards

Poly(vinyl alcohol) is produced mainly in five molecular weight ranges. Industry practice expresses the molecular weight of a particular grade in terms of the viscosity of a 4% aqueous solution. An unlimited number of viscosities can be generated by blending the available molecular weights. Products having different degree of hydrolysis can also be blended to obtain a particular performance characteristic. Poly(vinyl alcohol) is an innocuous material having unlimited storage stability.

Health and Safety Factors

Poly(vinyl alcohol) is a nonhazardous material according to the American Standard for Precautionary Labeling of Hazardous Industrial Chemicals (ANSI 2129.1-1976). Extensive tests indicate a very low order of oral toxicity. Short-term inhalation of PVA dust has no known health significance, but can cause discomfort and should be avoided in accordance with industry standards for exposure to nuisance dust. During transport and handling, granular PVA may form an explosive mixture with air, which shows a low severity rating (Bureau of Mines Rating) of 0.1 on a scale in which coal dust has a rating of 1.0.

Uses

The main applications for PVA are in textile sizing, adhesives, polymerization stabilizers, paper coating, poly(vinyl butyral), and PVA fibers. In terms of percentage, and omitting the production of PVA not isolated prior to conversion into poly(vinyl butyral), the principal applications are textile sizes, at 30%; adhesives, including use as a protective colloid, at 25%; fibers, at 15%; paper sizes, at 15%, poly(vinyl butyral), at 10%; and others, at 5%, which include water-soluble films, nonwoven fabric binders, thickeners, slow-release binders for fertilizer, photoprinting plates, sponges for cosmetic, and health care applications.

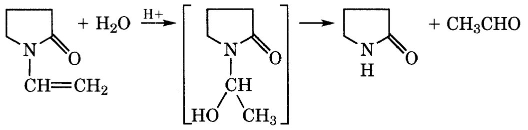
***N*-VINYLAMIDE POLYMERS.** *N*-Vinylamide-based polymers, especially the *N*-vinyllactams, such as poly(*N*-vinyl-2-pyrrolidinone) or simply polyvinylpyrrolidinone (PVP), continue to be of major importance to formulators of personal-care, pharmaceutical, agricultural, and industrial products because of desirable performance attributes and very low toxicity profiles. Because of hydrogen bonding of water to the amide group, many of the *N*-vinylamide homopolymers are water-soluble or dispersible. Like proteins, they contain repeating (but pendant) amide (lactam) linkages and share several protein-like characteristics. Many studies have actually employed PVP as a substitute for proteins, e.g., in simplifying the chemistry of the effects of radiation on polymers. Proteins are extremely complicated molecules with not only sequence distribution but tertiary bonding and structural complexity and it is an oversimplification to compare them to PVP, but the effects of radiation on PVP can be more readily studied. PVP can even be considered as a uniform synthetic protein-like analogue. By itself it does not enter into intermolecular hydrogen bonding, thus affording low viscosity concentrates, and also, unlike the proteins, PVP is soluble in polar solvents like alcohol. But even given these differences, the chemistry of PVP, the most commercially successful polymer of the class, is in many respects similar to that of proteins because of amide linkages sharing with them complexation to large anions such as polyphenols, anionic dyes, and surfactants. In addition to the ability to complex, PVP and its analogues along with a large assortment of copolymers are excellent film-formers. They exhibit the ability to interact with a variety of surfaces by hydrogen or electrostatic bonding, resulting in protective coatings and adhesive applications of commercial significance such as hair-spray fixatives, tablet binders, disintegrants, iodophors, antidye redeposition agents in detergents, protective colloids, dispersants, and solubilizers, among many others.

Monomers

N-Vinylamides and *N*-vinylimides can be prepared by reaction of amides and imides with acetylene, by dehydration of hydroxyethyl derivatives, by pyrolysis of ethylidenebisamides, or by vinyl exchange, among other methods; the monomers are stable when properly stored. Only *N*-vinyl-2-pyrrolidinone (VP) is of significant commercial importance. Vinylcaprolactam is available and is growing in importance, and vinyl formamide is available as a developmental monomer.

***N*-Vinyl-2-Pyrrolidinone.** Commonly called vinylpyrrolidinone or VP, *N*-vinyl-2-pyrrolidinone is a clear, colorless liquid that is miscible in all proportions with water and most organic solvents. It can polymerize slowly by itself but can be easily inhibited by small amounts of ammonia, sodium hydroxide (caustic pellets), or antioxidants such as *N*, *N′*-di-*sec*-butyl-*p*-phenylenediamine. It is stable in neutral or basic aqueous solution but readily hydrolyzed in the presence of acid to form 2-pyrrolidinone and acetaldehyde. Properties are given in Table 1.



Commercially available VP is usually over 99% pure but does contain several methyl-substituted homologues and 2-pyrrolidinone. The vinylation of 2-pyrrolidinone is carried out under alkaline catalysis analogous to the vinylation of alcohols. 2-Pyrrolidinone is treated with ca 5% potassium hydroxide, then water and some pyrrolidinone are distilled at reduced pressure. A ca 1:1 mixture (by vol) of acetylene and nitrogen is heated at 150–160°C and ca 2 MPa (22 atm). Fresh 2-pyrrolidinone and catalyst are added continuously while product is withdrawn. Conversion is limited to ca 60% to avoid excessive formation of by-products. The *N*-vinyl-2-pyrrolidinone is distilled at 70–85°C at 670 Pa (5 mm Hg) and the yield is 70–80%.

One of the manufacturers, ISP, recommends that an appropriate workplace exposure limit be set at 0.1 ppm (vapor). In case of accidental eye contact, immediately flush with water for at least 15 minutes and seek medical attention.

Homopolymerization of *N*-Vinyl-2-Pyrrolidinone

Ammonia H_2O_2 Initiation. The lower molecular weight grades (K-15 and K-30) of PVP are prepared industrially with an ammonia/H_2O_2 initiation system. Such products are the standards for the pharmaceutical industry and conform to the various national pharmacopeias.

[a] To convert Pa to mm Hg, multiply by 0.0075.

Organic Peroxides and Azo Initiation. The H_2O_2/ammonia initiation system is not employed commercially in the manufacture of higher molecular weight homologues; they are prepared with organic initiators. Such polymerizations follow simple chain theory and are usually performed in water commercially. The rate of polymerization is at a maximum in aqueous media at pH 8–10 and at 75 wt % monomer. Polymerization rates follow the polarity and hydrogen bonding capability of the solvent.

Cationic Polymerization. VP polymerizes to low molecular weight (oligomers) with typical cationic initiators, such as boron trifloride etherate. This reaction requires high concentrations, if not neat, of monomer and scrupulously anhydrous conditions for high yields; VP will readily hydrolyze to 2-pyrrolidinone and acetaldehyde even in the presence of trace moisture when catalyzed by strongly acidic reagents.

Proliferous Polymerization. Early attempts to polymerize VP anionically resulted in proliferous or "popcorn" polymerization. This was found to be a special form of free-radical addition polymerization, and not an example of anionic polymerization, as originally thought. VP contains a relatively acidic proton alpha to the pyrrolidinone carbonyl. In the presence of strong base such as sodium hydroxide, VP forms cross-linkers *in situ*. Both ethylidene vinyl pyrrolidinone (EVP) and ethylidene-bis-vinylpyrrolidinone (EBVP) are generated in about a 10:1 ratio, respectively. At the temperature required to generate these cross-linkers and when their concentration reaches some minimum level, usually a few percent, proliferous polymerization begins.

Crospovidones are produced commercially by two processes, i.e., *in situ* generation of cross-linker or addition of divinylimidazoline, and they are indistinguishable by ir. Both types exhibit a T_g of 190–195°C, which is not that much above the 175°C of high molecular weight, soluble PVP. Proliferous polymers prepared with easily hydrolyzed cross-linker containing an imine linkage do not further swell even when the cross-links are hydrolyzed. The crospovidones are unusually high molecular weight, highly chain-entangled polymers having covalent cross-links that most likely retard the termination reaction during polymerization and are not entirely responsible for the resulting mechanical properties, such as swell ratio.

The crospovidones are easily compressed when anhydrous but readily regain their form upon exposure to moisture. This is an ideal situation for use in pharmaceutical tablet disintegration and they have found commercial application in this technology. PVP strongly interacts with polyphenols, the crospovidones can readily remove them from beer, preventing subsequent interaction with beer proteins and the resulting formation of haze. The resin can be recovered and regenerated with dilute caustic.

PVP Hydrogels

Cross-linked versions of water-soluble polymers swollen in aqueous media are broadly referred to as hydrogels and have a growing commercial utility in such applications as oxygen-permeable soft contact lenses and

controlled-release pharmaceutical drug delivery devices. Cross-linked PVP and selected copolymers fit this definition and are of interest because of the following structure/performance characteristics:

Structure	Performance	Benefit
nonionic	compatibility with other ingredients	stable formulation
pyrrolidinone	low toxicity	nonirritating/ nonthrombogenic
	complexation–actives/O_2	controlled release-transport
	high T_g	mechanical stability
	hydrolytic stability	storage-stable
ethylene backbone	nonbiodegradable, hydrolytic stability	resists biocontamination storage-stable
cross-links	swell volume/viscosity	mechanical stability/diffusion control

Cross-linked PVP can be prepared by several routes other than proliferous polymerization PPVP (crospovidones). Although a hydrogel, the swell volume of this type of polymer cannot be controlled over a large increment because the granular particles cannot be formed into larger uniform assemblies. These limitations can be overcome by the polymerization of VP in the presence of a few percent of suitable cross-linker utilizing standard free-radical initiation. The solution to this problem is to balance the reactivity ratios of the cross-linker and other comonomers with those of VP to obtain uniform copolymerization and cross-linking.

Cross-linked PVP can also be obtained by cross-linking the preformed polymer chemically (with persulfates, hydrazine, or peroxides) or with actinic radiation. If the starting PVP homopolymer is too low in molecular weight or too dilute, cyclization or cleavage is preferred.

Poly(*N*-Vinyl-2-Pyrrolidinone)

Poly(*N*-vinyl-2-pyrrolidinone) (PVP) is undoubtedly the best-characterized and most widely studied *N*-vinyl polymer. It derives its commercial success from its biological compatibility, low toxicity, film-forming and adhesive characteristics, unusual complexing ability, relatively inert behavior toward salts and acids, and thermal and hydrolytic stability.

Poly(*N*-vinyl-2-pyrrolidinone) is described in the *U.S. Pharmacopeia* as consisting of linear *N*-vinyl-2-pyrrolidinone groups of varying degrees of polymerization. The molecular weights of PVP samples are determined by size exclusion chromatography (sec), osmometry, ultracentrifugation, light-scattering, and solution viscosity techniques. The most frequently employed method of determining and reporting the molecular weight of PVP samples utilizes the sec/low angle light scattering (lalls) technique. A frequently used and commonly recognized method of distinguishing between different molecular weight grades of PVP is the K value. The relative viscosity is obtained with an Ostwald-Fenske or Cannon-Fenske capillary viscometer, and the K value is derived from Fikentscher's equation.

$$\log \frac{\eta_{\text{rel}}}{c} = \frac{75K_0^2}{1 + 1.5K_0c} + K_0 \qquad (1)$$

where $K = 1000\ \text{K}_0$, η_{rel} = relative viscosity, and c = concentration of the solution in g/100 mL. Solving directly for K, the Fikentscher equation is converted to:

$$K = [300c \log Z + (c + 1.5c \log Z)^2 + 1.5c \log Z - c]/(0.15c + 0.0003c^2)$$

where $Z = \eta_{\text{rel}}$.

Specifications for Pharmaceutical grade is given in Table 2.

The T_g of PVP is sensitive to residual moisture and unreacted monomer. It is even sensitive to how the polymer was prepared, suggesting that MWD, branching, and cross-linking may play a part. Polymers presumably with the same molecular weight prepared by bulk polymerization exhibit lower T_gs compared to samples prepared by aqueous solution polymerization, lending credence to an example of branching caused by chain-transfer to monomer.

TABLE 2. SPECIFICATIONS OF PHARMACEUTICAL PVP GRADES (POVIDONE)

Assay	Value (max)
K value	
10–15	85–115%[a]
16–90	90–107%[a]
moisture, %	5
pH[b]	3.0–7.0
residue on ignition, %	0.02
aldehydes, %[c]	0.02
N-vinyl-2-pyrrolidinone, %	0.20
lead, ppm	10
arsenic, ppm	1
nitrogen, %	11.5–12.8

[a] Of stated supplier's value.
[b] Of a 5% solution in distilled water.
[c] Calculated as acetaldehyde.

Molecular weight also plays a significant role in T_g, which increases to a limiting value of 180°C for high purity samples above K-90 in molecular weight. The following equation applies:

$$T_g(^\circ\text{C}) = 175 - \frac{9685}{K^2}$$

One of PVP's more outstanding attributes is its solubility in both water and a variety of organic solvents. PVP is soluble in alcohols, acids, ethyl lactate, chlorinated hydrocarbons, amines, glycols, lactams, and nitroparaffins. PVP is insoluble in hydrocarbons, ethers, ethyl acetate, *sec*-butyl-4-acetate, 2-butanone, acetone, cyclohexanone, and chlorobenzene.

Complexation

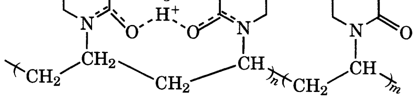
The combination of electrostatic interaction (induced dipole—dipole interaction) with an increase in entropy resulting from the discharge of bound water is fundamental to PVP's ability to complex with a variety of large anions.

Other factors that can stabilize such a forming complex are hydrophobic bonding by a variety of mechanisms (Van der Waals, Debye, ion—dipole, charge-transfer, etc). Such forces complement the stronger hydrogen-bonding and electrostatic interactions.

Approximately a minimum $\overline{M}_n$ of 1 to 5,000 is required before complexation is no longer dependent on molecular weight for small anions such as KI_3 and 1-anilinonaphthaline-8-sulfonate (ANS).

Equilibrium dialysis studies indicate around 10 repeat VP units (base moles) are required to form favorable complexes. This figure can rise to several hundred for methyl orange and other anions depending on structure.

Iodine Complexes. The small molecule/PVP complex between iodine and PVP is probably the best-known example and can be represented as follows:



It is widely employed as a disinfectant in medicine (Povidone-iodine) because of its mildness, low toxicity, and water solubility. According to the *U.S. Pharmacopeia*, Povidone-iodine is a free-flowing, brown powder that contains from 9–12% available iodine. It is soluble in water and lower alcohols. When dissolved in water, the uncomplexed free iodine level is very low; however, the complexed iodine acts as a reservoir and by equilibrium replenishes the free iodine to the equilibrium level. This prevents free iodine from being deactivated because the free form is continually available at effective biocidal levels from this large reservoir. PVP will interact with other small anions and resembles serum albumin and other proteins in this regard. It can be "salted in" with anions such as NaSCN or "out" with Na_2SO_4 much like water-soluble proteins.

Phenolics. PVP readily complexes phenolics of all types to some degree, the actual extent depending on structural features such as number and orientation of hydroxyls and electron density of the associated aromatic system. A model has been proposed. Complexation with phenolics can result in reduced PVP viscosity and even polymer-complex precipitation.

One practical result of this strong interaction is the employment of PVP to remove unwanted phenolics such as bitter tanins from beer and wine.

Dyes. PVP is currently (ca 1997) employed in a variety of antidye redeposition detergents as a result of its strong interaction with fugitive anionic dyes. This interaction depends on the structure of the dye. Cationic dyes complex only if they also contain hydrogen-bonding functionality. Anionic dyes complex more easily, depending on the number of anionic groups, size of the aromatic nucleolus, and number and orientation of phenolic hydroxyl groups, etc.

Anionic Surfactants. PVP also interacts with anionic detergents, another class of large anions. The addition of PVP results in the formation of micelles at lower concentration than the critical micelle concentration (CMC) of the free surfactant the mechanism is described as a "necklace" of hemimicelles along the polymer chain, the hemimicelles being surrounded to some extent with PVP. The effective lowering of the CMC increases the surfactant's apparent activity at interfaces. PVP will increase foaming of anionic surfactants for this reason. Because of this interaction, PVP has found application in surfactant formulations.

Polymer/Polymer Complexes. PVP complexes with other polymers capable of interacting by hydrogen-bonding, ion-dipole, or dispersion forces. The interest in compatibility on a molecular level, an interesting phenomenon rarely found to exist between dissimilar polymers, is favored by the ability of PVP to form polymer/polymer complexes. Practical applications have been reported for PVP/cellulosics and PVP/polysulfones in membrane separation technology. Electrically conductive polymers of polyaniline are rendered more soluble and hence easier to process by complexation with PVP. Addition of small amounts of PVP to nylon 66 and 610 causes significant morphological changes, resulting in fewer but more regular spherulites.

Copolymerization

Copolymerizations can be conveniently carried out in aqueous solution or in a variety of solvents, depending on monomer/polymer solubilities. Various strategies have been employed to compensate for the divergence in reactivity ratios in order to form uniform (statistical) copolymers such as semibatch or mixed monomer feeds, the goal being to add the more reactive monomer at the rate at which it is being consumed. Clearly, if the difference in reactivity is too great, then the amount of more reactive monomer that can be uniformly incorporated is significantly reduced.

Poly(Vinylpyrrolidinone-co-Vinyl Acetate). The first commercially successful class of VP copolymers, poly(vinylpyrrolidinone-co-vinyl acetate) is currently manufactured in sizeable quantities. A wide variety of compositions and molecular weights are available as powders or as solutions in ethanol, isopropanol, or water (if soluble).

An important reason for the ongoing interest in these copolymers is that vinyl acetate reduces hydrophilicity so that applications that require less moisture-sensitive films such as those employed to set hair are less prone to plasticize and become tacky under high humidity conditions.

Desirable fixative properties superior to PVP homopolymer can be specified by judicious selection of the amount of vinyl acetate. Hair sprays are limited in the molecular weight of the resin because if they are too high the resulting viscosity of the formulation will result in a poor (coarse) spray pattern. Increasing the VP/VA ratio causes properties to increase in the direction shown by the arrows. Other applications for VP/VA copolymers are uses as water-soluble or remoistenable hot melt adhesives, pharmaceutical tablet coatings, binders, and controlled-release substrates.

Tertiary Amine-Containing Copolymers. Copolymers based on DMAEMA (dimethylaminoethyl methacrylate) in either free amine form or quaternized with diethyl sulfate or methyl chloride have achieved commercial significance as fixatives in hair-styling formulations, especially in the well-publicized "mousses" or as hair-conditioning shampoo additives.

The most successful of these products contain high ratios of VP to DMAEMA and are partially quaternized with diethyl sulfate (Polyquaternium 11). They afford very hard, clear, lustrous, nonflaking films on the hair that are easily removed by shampooing. More recently, copolymers with methylvinylimidazolium chloride (Polyquaternium 16) or MAPTAC (methacrylamidopropyltrimethyl ammonium chloride) (Polyquaternium 28) have been introduced. Unquaternized DMAEMA copolymers afford resins that are mildly cationic and less hydroscopic.

Copolymers Containing Carboxylic Groups. A new line of VP/acrylic acid copolymers in powdered form prepared by precipitation polymerization from heptane have been introduced commercially. A wide variety of compositions and molecular weights are available, from 75/25 to 25/75 wt % VP/AA and from 20×10^3 to 250×10^3 molecular weights.

The copolymers are insoluble in water unless they are neutralized to some extent with base. They are soluble, however, in various ratios of alcohol and water, suggesting applications where delivery from hydroalcoholic solutions but subsequent insolubility in water is desired, such as in low volatile organic compound (VOC) hair-fixative formulations or tablet coatings. Unneutralized, their T_gs are higher than expected, indicating interchain hydrogen bonding.

Miscellaneous Copolymers. VP has been employed as a termonomer with various acrylic monomer—monomer combinations, especially to afford resins useful as hair fixatives.

TABLE 3. PROPERTIES AND APPLICATIONS OF COMMERCIAL PVPs

Polymer	Properties/applications
	Homopolymers
PVP	film former, adhesive, binder, complexant, stabilizer, crystallization inhibitor, dye scavenger, detoxicant, viscosity modifier
	Cross-linked
proliferous polymerization	pharmaceutical tablet disintegrant, adsorbent for polyphenols (tanins), beverage clarification
	Copolymers
PVP/VA	film-forming adhesives for hair preparations, bio-adhesives, water-remoistenable or removable adhesives
PVP/DMAEMA	mildly cationic, hair styling aids and conditioners with strong hold; substantive, lustrous film-formers
PVP/DMAEMA DES quaternary	strongly cationic, substantive, hair fixative ingredients
PVP/imidazolinum quaternary	
PVP/styrene[a]	opacifier for personal care products; stable styrene emulsion
PVP/alpha-olefins[a]	surface-active film formers; waterproofing of sunscreens
	Terpolymers
VP/VCl/DMAEMA	cationic water-soluble hair styling aid
VP/tBMA/MA	hair fixatives

[a] Graft copolymers.

Applications

An overview of the various product categories is given in Table 3.

VINYL CHLORIDE. Vinyl chloride, [CAS: 75-01-4] $CH_2{=}CHCl$, by virtue of the wide range of application for its polymers in both flexible and rigid forms, is a major commodity chemical in the U.S. and an important item of international commerce. Growth in vinyl chloride production is directly related to demand for its polymers and, on an energy-equivalent basis, rigid poly(vinyl chloride) (PVC) is one of the most energy-efficient construction materials available.

Vinyl chloride (also known as chloroethylene or chloroethene) is a colorless gas at normal temperature and pressure, but is typically handled

as the liquid (bp −13.4°C). However, no human contact with the liquid is permissible. Vinyl chloride is an OSHA-regulated material.

Physical Properties

The physical properties of vinyl chloride are listed in Table 1. Vinyl chloride and water are nearly immiscible. Vinyl chloride is soluble in hydrocarbons, oil, alcohol, chlorinated solvents, and most common organic liquids.

Reactions

Polymerization. The most important reaction of vinyl chloride is its polymerization and copolymerization in the presence of a radical-generating initiator.

Substitution at the Carbon–Chlorine Bond. Vinyl chloride is generally considered inert to nucleophilic replacement compared to other alkyl halides. However, the chlorine atom can be exchanged under nucleophilic conditions in the presence of palladium and certain other metal chlorides and salts. Vinyl alcoholates, esters, and ethers can be readily produced from these reactions. Vinylmagnesium chloride (Grignard reagent) can be prepared from vinyl chloride and then used to make a variety of useful end products or intermediates by adding a vinyl anion to organic functional groups. Vinyl chloride similarly undergoes Grignard reactions with other organomagnesium halide compounds. Vinyllithium, another reactive intermediate, can be formed directly from vinyl chloride by means of a lithium dispersion. Vinyl chloride reacts with sulfides, thiols, alcohols, and oximes in basic media. Reaction of vinyl chloride with hydrogen fluoride over a chromia on alumina catalyst yields vinyl fluoride. The carbon–chlorine bond can also be activated at high temperatures.

Oxidation. The chlorine atom-initiated, gas phase oxidation of vinyl chloride yields 74% formyl chloride and 25% CO at high oxygen to Cl_2 ratios. It is unique among chloro olefin oxidations because CO is a major initial product and because the reaction proceeds by a nonchain path. The oxidation of vinyl chloride with oxygen in the gas phase proceeds by a nonradical path which, again, is unique among the chloro olefins. No C_2 carbonyl compounds are made; the major products are formyl chloride, CO, HCl, and formic acid. Oxidation of vinyl chloride with ozone in either the liquid or the gas phase gives formic acid and formyl chloride. Vinyl chloride can be completely oxidized to CO_2 and HCl using potassium permanganate in an aqueous solution at pH 10. The combustion of vinyl chloride in air produces mainly CO_2 and HCl, along with CO and a trace of phosgene.

Addition. Vinyl chloride undergoes a wide variety of addition reactions. Chlorine adds to vinyl chloride to form 1,1,2-trichloroethane by either an ionic or a radical path. Hydrogen halides add to vinyl chloride, usually to yield the 1,1-adduct. Many other vinyl chloride adducts can be formed under acid-catalyzed Friedel-Crafts conditions. Vinyl chloride can be hydrogenated to ethyl chloride and ethane over a platinum on alumina catalyst.

Photochemistry. Vinyl chloride is subject to photodissociation. Photoexcitation at 193 nm results in the elimination of HCl fragments and Cl atoms in an approximately 1.1:1 ratio. Both vinylidene and acetylene have been observed as photolysis products, as have H_2 molecules and H atoms.

Pyrolysis. Vinyl chloride is more stable than saturated chloroalkanes to thermal pyrolysis. That is why nearly all vinyl chloride made commercially comes from thermal dehydrochlorination of ethylene dichloride (EDC). When vinyl chloride is heated to 450°C, only small amounts of acetylene form. Decomposition of vinyl chloride via a free-radical chain process begins at approximately 550°C, and increases with increasing temperature. Acetylene, HCl, chloroprene, and vinylacetylene are formed in about 35% total yield at 680°C. At higher temperatures, tar and soot formation becomes increasingly important. When dry and in contact with metals, vinyl chloride does not decompose below 450°C. However, if water is present, vinyl chloride can corrode iron, steel, and aluminum because of the presence of trace amounts of HCl. This HCl may result from the hydrolysis of the peroxide formed between oxygen and vinyl chloride.

TABLE 1. PHYSICAL PROPERTIES OF VINYL CHLORIDE

Manufacture

Vinyl chloride monomer was first produced commercially in the 1930s from the reaction of HCl with acetylene derived from calcium carbide. After ethylene became plentiful in the early 1950s, commercial processes were developed to produce vinyl chloride from ethylene and chlorine. These processes included direct chlorination of ethylene to form EDC, followed by pyrolysis of EDC to make vinyl chloride. However, because the EDC cracking process also produced HCl as a coproduct, the industry did not expand immediately, except in conjunction with acetylene-based technology. The development of ethylene oxychlorination technology in the late 1950s encouraged new growth in the vinyl chloride industry. In this process, ethylene reacts with HCl and oxygen to form EDC. Combining the component processes of direct chlorination, EDC pyrolysis, and oxychlorination provided the so-called balanced process for production of vinyl chloride from ethylene and chlorine with no net consumption or production of HCl.

Although a small fraction of the world's vinyl chloride capacity is still based on acetylene or mixed acetylene–ethylene feedstocks, nearly all production is conducted by the balanced process based on ethylene and chlorine. The reactions for each of the component processes are shown in equations 1–3 and the overall reaction is given by equation 4:

$$\textit{Direct chlorination}\ CH_2{=}CH_2 + Cl_2 \longrightarrow ClCH_2CH_2Cl \quad (1)$$

$$\textit{EDC pyrolysis}\ 2\ ClCH_2CH_2Cl \longrightarrow 2\ CH_2{=}CHCl + 2\ HCl \quad (2)$$

$$\textit{Oxychlorination}\ CH_2{=}CH_2 + 2\ HCl + 1/2\ O_2 \longrightarrow ClCH_2CH_2Cl + H_2O \quad (3)$$

$$\textit{Overall reaction}\ 2\ CH_2{=}CH_2 + Cl_2 + 1/2\ O_2 \longrightarrow 2\ CH_2{=}CHCl + H_2O \quad (4)$$

Direct chlorination of ethylene is usually conducted in liquid EDC in a bubble column reactor. Under typical process conditions, the reaction rate is controlled by mass transfer, with absorption of ethylene as the limiting factor. Ferric chloride is a highly selective and efficient catalyst for this reaction, and is widely used commercially. The direct chlorination process may be run with a slight excess of either ethylene or chlorine, depending on how effluent gases from the reactor are subsequently processed. Conversion of the limiting component is essentially 100%, and selectivity to EDC is greater than 99%. The direct chlorination reaction is exothermic ($\Delta H = -180$ kJ/mol for eq. 1) and requires heat removal for temperature control.

One widely used method involves operating the reactor at the boiling point of EDC, allowing the pure product to vaporize, and then either recovering heat from the condensing vapor or replacing one or more EDC fractionation column reboilers with the reactor itself.

In oxychlorination, ethylene reacts with dry HCl and either air or pure oxygen to produce EDC and water. While commercial oxychlorination processes may differ from one another to some extent because they were developed independently by many different vinyl chloride producers, in each case the reaction is carried out in the vapor phase in either a fixed- or fluidized-bed reactor containing a modified Deacon catalyst. Cupric chloride is usually the primary active ingredient of the catalyst, supported on a porous substrate such as alumina, silica–alumina, or diatomaceous earth. The oxychlorination reaction is highly exothermic ($\Delta H = -239$ kJ/mol for eq. 3) and requires heat removal for temperature control.

Fluidized bed reactors typically are vertical cylindrical vessels equipped with a support grid and feed sparger system for adequate fluidization and feed distribution, internal cooling coils for heat removal, and either external or internal cyclones to minimize catalyst carryover. Fluidization of the catalyst assures intimate contact between feed and product vapors, catalyst, and heat-transfer surfaces, and results in a uniform temperature within the reactor. Reaction heat can be removed by generating steam within the cooling coils or by some other heat-transfer medium.

Fixed-bed reactors resemble multitube heat exchangers, with the catalyst packed in vertical tubes held in a tubesheet at top and bottom. Reaction heat can be removed by generating steam on the shell side of the reactor or by some other heat-transfer fluid. However, temperature control is more difficult in a fixed-bed than in a fluidized-bed reactor because localized hot spots tend to develop in the tubes.

In the air-based oxychlorination process with either reactor type, ethylene and air are fed in slight excess of stoichiometric requirements to ensure high conversion of HCl and to minimize losses of excess ethylene that remains in the vent gas after product condensation. Under these conditions, typical feedstock conversions are 94–99% for ethylene and 98–99.5% for HCl with EDC selectivities of 94–97%. The use of oxygen instead of air in the oxychlorination process with either reactor type allows operation with excess ethylene and at lower temperatures. This enables recycling of unconverted ethylene, resulting in improved operating efficiency and product yield. An important advantage of oxygen-based oxychlorination technology over air-based operation is the drastic reduction in volume of the vent gas discharged. Since nitrogen is no longer present in the reactor feed streams, only a small amount of purge gas (about 2–5% of the vent gas volume for air-based operation) is vented.

Direct chlorination usually produces EDC with a purity greater than 99.5 wt %, so that, except for removal of the $FeCl_3$, little further purification is needed before it can be cracked. EDC from the oxychlorination process, however, is less pure and requires purification by distillation.

Thermal pyrolysis or cracking of EDC to vinyl chloride and HCl occurs as a vapor-phase, homogeneous, first-order, free-radical chain reaction. The endothermic cracking of EDC ($\Delta H = 71$ kJ/mol EDC reacted for eq. 2) is relatively clean at atmospheric pressure and at temperatures of 425–550°C. Commercial pyrolysis units, however, generally operate at gauge pressures of 1.4–3.0 MPa (200–435 psig) and at temperatures of 475–525°C to provide for better heat transfer and reduced equipment size, and to allow separation of HCl from vinyl chloride by fractional distillation at noncryogenic temperatures. EDC conversion per pass through the pyrolysis reactor is normally maintained at 53–63%. Cracking reaction selectivity to vinyl chloride of $> 99\%$ can be achieved at these conditions. Increasing cracking severity beyond this level gives progressively smaller increases in EDC conversion, with progressively lower selectivity to vinyl chloride. Higher conversion also increases pyrolysis tube coking rates and causes problems with downstream product purification. To minimize coke formation, it is necessary to quench or cool the pyrolysis reactor effluent quickly. Therefore, the hot effluent gases are normally quenched and partially condensed by direct contact with cold EDC in a quench tower. Alternatively, the pyrolysis effluent gases can first be cooled by heat exchange with cold liquid EDC furnace feed in a transfer line exchanger (TLE) prior to quenching in the quench tower.

Quenched pyrolysis product is typically distilled to remove first HCl and then vinyl chloride. The vinyl chloride is usually further treated to produce specification product, recovered HCl is sent to the oxychlorination process, and unconverted EDC is purified for removal of by-products before it is recycled to the cracking furnace.

By-product disposal from vinyl chloride manufacturing plants is complicated by the need to process a variety of gaseous, organic liquid, aqueous, and solid streams, while ensuring that no chlorinated organic compounds are inadvertently released. Each class of by-product streams requires its own treatment and disposal system.

Vent streams from the different unit operations may contain traces (or more) of HCl, CO, methane, ethylene, chlorine, and vinyl chloride. The common treatment method is either incineration or catalytic combustion, followed by removal of HCl from the effluent gas. Organic liquid streams contain a variety of chlorinated compounds. When there is economic justification, these streams can be fractionated to recover specific, useful components, and the remainder subsequently incinerated and scrubbed to remove HCI. Alternative methods include catalytic oxidation or combustion, and may involve recycle of HCI to oxychlorination and recovery of the heat of combustion to make high pressure steam. Process water streams from vinyl chloride manufacture are typically steam-stripped to remove volatile organics, neutralized, and then treated in a conventional wastewater treatment process. Solid by-products include sludge from wastewater treatment, spent catalyst, and coke from the EDC pyrolysis process. These need to be disposed of in an environmentally sound manner, e.g., by sludge digestion, incineration, landfill, etc.

Environmental Considerations

Since the early 1980s, there has been much debate among environmental activist organizations, industry, and government about the impact of chlorine chemistry on the environment. One aspect of this debate involves the incidental manufacture and release of trace amounts of hazardous compounds such as polychlorinated dibenzodioxins, dibenzofurans, and biphenyls (PCDDs, PCDFs, and PCBs, respectively, but often referred to collectively as dioxins) during the production of chlorinated compounds like vinyl chloride. In 1994, the EPA released a review draft of its reassessment of the impact of dioxins in the environment on human health, which prompted speculation as to the amount of dioxins that might be attributed to chlorine-based industrial processes. The U.S. vinyl industry responded by committing to a voluntary characterization of dioxin levels in its products and in emissions from its facilities to the environment. The results of this study to date support the vinyl industry's position that it is a minor source of dioxins in the environment. In addition, a global benchmark study released recently by the American Society of Mechanical Engineers found no relationship between the chlorine content of waste and dioxin emissions from combustion processes.

Because of the toxicity of vinyl chloride, the EPA in 1975 proposed emission standards for vinyl chloride manufacture. This proposal was subsequently enacted as EPA Regulation 40 CFR 61, Subpart F. Compliance testing began in 1978. Environmental concerns and government regulations have prompted a major increase in the amount of add-on technology used in U.S. vinyl chloride production plants.

Technology Trends

The ethylene-based, balanced vinyl chloride process, which accounts for nearly all capacity worldwide, has been practiced by a variety of vinyl chloride producers since the mid-1950s. The technology is mature, so that the probability of significant changes is low. New developments in production technology will likely be based on incremental improvements in raw material and energy efficiency, environmental impact, safety, and process reliability.

More recent trends include widespread implementation of oxygen-based oxychlorination, further development of new catalyst formulations, a broader range of energy recovery applications, a continuing search for ways to improve conversion and minimize by-product formation during EDC pyrolysis, and chlorine source flexibility. The application of computer model-based process control and optimization is growing as a way to achieve even higher levels of feedstock and energy efficiency and plant process reliability.

Health and Safety Factors

Vinyl chloride is an OSHA-regulated substance. Current OSHA regulations impose a permissible exposure limit (PEL) to vinyl chloride vapors of no

more than 1.0 ppm averaged over any 8-h period. Short-term exposure is limited to 5.0 ppm averaged over any 15-min period. Wherever exposure is above the OSHA limit, respirators are required. Contact with liquid vinyl chloride is prohibited.

Chronic exposure to vinyl chloride at concentrations of 100 ppm or more is reported to have produced Raynaud's syndrome, lysis of the distal bones of the fingers, and a fibrosing dermatitis. However, these effects are probably related to continuous intimate contact with the skin. Chronic exposure to large amounts of vinyl chloride gas over a period of many years is also reported to have produced a rare cancer of the liver (angiosarcoma) in a small number of workers.

Vinyl chloride also poses a significant fire and explosion hazard. It has a wide flammability range, from 3.6% to 33.0% by volume in air. Large fires of the compound are very difficult to extinguish, while vapors represent a severe explosion hazard.

Vinyl chloride is generally transported via pipeline, and in railroad tank cars and tanker ships. Because hazardous peroxides can form on standing in air, especially in the presence of iron impurities, vinyl chloride should always be handled and transported under an inert atmosphere.

Uses

Vinyl chloride has gained worldwide importance because of its industrial use as the precursor to PVC. It is also used in a wide variety of copolymers. The inherent flame-retardant properties, wide range of plasticized compounds, and low cost of polymers from vinyl chloride have made it a significant industrial chemical. About 95% of current vinyl chloride production worldwide ends up in polymer or copolymer applications. Vinyl chloride also serves as a starting material for the synthesis of a variety of industrial compounds. The primary nonpolymeric uses of vinyl chloride are in the manufacture of vinylidene chloride and tri- and tetrachloroethylene.

VINYL CHLORIDE POLYMERS. Poly(vinyl chloride) (PVC), commanding large and broad uses in commerce, is second in volume only to polyethylene, having a volume sales in North America in 1995 of 6.2×10^9 kg(13.7×10^9 lb). Vinyl compounds usually contain close to 50% chlorine, which not only provides no fuel, but acts to inhibit combustion in the gas phase, thus supplying the vinyl with a high level of combustion resistance, useful in many building as well as electrical housings and electrical insulation applications.

PVC has a unique ability to be compounded with a wide variety of additives, making it possible to produce materials that range from flexible elastomers to rigid compounds, that are virtually unbreakable. Compounds are also made that have stiff melts for profile extrusion or low viscosity melts for thin-walled injection molding.

Produced by free radical polymerization, PVC has the structure of $-(CH_2CHCl)-_n$, where the degree of polymerization, n, ranges from 500 to 3500.

PVC Morphology

The principal type of polymerization of PVC is the suspension polymerization route. The morphology formed during polymerization strongly influences the processibility and physical properties.

In the suspension polymerization of PVC, droplets of monomer 30–150 μm in diameter are dispersed in water by agitation. A thin membrane of a graft copolymer of poly(vinyl chloride) and poly(vinyl alcohol) is formed at the H_2O–monomer interface. Primary particles, 1 μm in diameter, deposit onto the membrane from the monomer side.

Mass-polymerized PVC also has a skin of compacted PVC primary particles very similar in thickness and appearance to the suspension-polymerized PVC skin. However, mass PVC does not contain the thinblock copolymer membrane.

In suspension PVC polymerization, droplets of polymerizing PVC, 30–150-μm dia agglomerate to form grains at 100–200-μm dia. With one droplet per grain, the shape is quite spherical. With several droplets making up the grain, the shape can be quite irregular and knobby. The grain shape plays an important role in determining grain packing and bulk density of a powder.

For both suspension and mass polymerizations at less than 2% conversion, PVC precipitates from its monomer as stable primary particles, slightly below 1-μm dia.

On an even smaller scale is the microdomain structure at 0.01-μm spacing. This is interpreted as a structure where the crystallites of about 0.01-μm spacing are tied together by molecules in the amorphous regions. Plasticizer swells the amorphous regions without dissolving the crystallites.

PVC has structure that is built upon structure which is, in turn, built upon even more structure. These many layers of structure are all important to performance and are interrelated. A summary of these structures is listed in Table 1.

The first step in processing is usually powder mixing in a high speed, intensive mixer. PVC resin, stabilizers, plasticizers, lubricants, processing aids, fillers, and pigments are added to the powder blend for distributive mixing.

In plasticized PVC, liquid plasticizers first fill the voids or pores in the PVC grains fairly rapidly during powder mixing. If a large amount of plasticizer is added, the excess plasticizer beyond the capacity of the pores initially remains on the surface of the grains, making the powder somewhat wet and sticky. Continued heating increases the diffusion rate of plasticizer into the PVC mass where the excess liquid is eventually absorbed and the powder dries.

PVC powder compounds are heated, sheared, and deformed during melt processing. During this process, the grains of PVC are broken down. A processing window of stable primary particles exists even with continued melt processing. The primary particle is about a billion molecules of PVC held together by a structure of crystallites and tie molecules.

The PVC crystallites are small, average 0.7 nm (3 monomer units), in the PVC chain direction, and are packed laterally to a somewhat greater extent.

PVC Fusion (Gelation). The PVC primary particle flow units (billion molecule bundles) can partially melt, freeing some molecules of PVC that can entangle at the flow unit boundary. These entangled molecules can recrystallize upon cooling, forming secondary crystallites, and tie the flow units together into a large three-dimensional structure. This process is known as fusion or gelation.

The strength created by the fusion process is strongly dependent on the previous processing temperature and the molecular weight of the PVC. PVC normally improves in properties with increasing fusion (or increasing melt temperature).

Plasticized PVC has the same structures as rigid PVC, except that plasticizer enters the amorphous phase of PVC and makes the tie molecules elastomeric. The grains break down to 1-μm primary particles which become the melt flow units. The crystallites are not destroyed by plasticizer. Table 2 provides a list of the PVC physical parameters.

Chemical Properties

The addition of vinyl monomer to a growing PVC chain can be considered to add in a head-to-tail fashion, resulting in a chlorine atom on every other carbon atom, i.e.,

$$-(CH_2CHClCH_2CHClCH_2CHCl)-_n$$

or in a head-to-head, tail-to-tail fashion, resulting in chlorine atoms on adjacent carbon atoms, i.e.,

$$-(CH_2CHClCHClCH_2CH_2CHClCHClCH_2)-_n$$

Dechlorination studies show that the head-to-tail structure is predominate.

TABLE 1. SUMMARY OF POLY(VINYL CHLORIDE) MORPHOLOGY

Feature	Size	Description
droplets	30–150 μm dia	dispersed monomer during suspension polymerization
membranes	0.01–0.02 μm thick	membrane at monomer–water interface in suspension PVC (usually graft copolymer of PVC and dispersant, such as poly(vinyl alcohol))
grains	100–200 μm dia	after polymerization, free-flowing powder usually made up of agglomerated droplets; in mass polymerization, is free-flowing powder
skins	0.5–5 μm thick	shell on grains made up of PVC deposited onto membrane during suspension polymerization; in mass polymerization, is PVC compacted on grain surface
primary particles	1 μm dia	formed as single polymerization site in both suspension and mass polymerization by precipitation of polymer from monomer; made up of over a billion molecules, it is often melt flow unit established during melt processing (in emulsion polymerization, it is emulsion particle)
agglomerates of primary particles	3–10 μm dia	formed during polymerization by merging of primary particles
domains	0.1 μm dia	formed under special conditions such as high temperature melting (205°C) followed by lower temperature mechanical work (140–150°C); water-phase polymerization also produces domain-sized structure
microdomains	0.01 μm spacing	crystallite spacing
secondary crystallinity	0.01 μm spacing	crystallinity reformed from amorphous melt and responsible for fusion (gelation)

Both saturated and unsaturated end groups can be formed during polymerization by chain transfer to monomer or polymer and by disproportionation.

PVC polymerization has a high chain-transfer activity to monomer; about 60% of the chains have unsaturated chain ends and the percentage of chain ends containing initiator fragments is low. Chain transfer to polymer leads to branching.

The addition of monomer fixes the tacticity of the previous monomer unit. The tacticity of PVC is nearly random, with syndiotacticity slightly favored at lower polymerization temperature.

Polymerization Kinetics of Mass and Suspension PVC. The polymerization kinetics of mass and suspension PVC are considered together because a droplet of monomer in suspension polymerization can be considered to be a mass polymerization in a very tiny reactor. During polymerization, the polymer precipitates from the monomer when the chain size reaches 10–20 monomer units. The precipitated polymer remains swollen with monomer, but has a reduced radical termination rate. This leads to a higher concentration of radicals in the polymer gel and an increased polymerization rate at higher polymerization conversion.

Polymerization in two phases, the liquid monomer phase and the swollen polymer gel phase, forms the basis for kinetic descriptions of PVC polymerization.

Chain transfer to monomer is the main reaction controlling molecular weight and molecular weight distribution. PVC molecular weights are usually determined in the United States using inherent viscosity or relative viscosity measured according to ASTM D1243.

PVC Resin Manufacturing Processes

Mass Polymerization. Mass or bulk polymerization of PVC is normally difficult. At high conversions the mixture becomes extremely viscous, impeding agitation and heat removal, causing a high polymerization temperature and broad molecular weight distribution. A two-stage process overcomes these problems. The first stage of the process, which forms a skeleton seed grain for polymerization in a second stage, is carried out in a prepolymerizer with flat blade agitator and baffles to about 7–10% conversion. The number of grains remain constant throughout this polymerization.

Suspension Polymerization. Suspension polymerization is carried out in small droplets of monomer suspended in water. The monomer is first finely dispersed in water by vigorous agitation. Suspension stabilizers act to minimize coalescence of droplets by forming a coating at the monomer-water interface. The hydrophobic-hydrophilic properties of the suspension stabilizers are key to resin properties and grain agglomeration.

Kinetics of suspension PVC are identical to the kinetics of mass PVC.

Emulsion Polymerization. Emulsion polymerization takes place in a soap micelle where a small amount of monomer dissolves in the micelle. The initiator is water-soluble. Polymerization takes place when the radical enters the monomer-swollen micelle. Termination takes place in the growing micelle by the usual radical–radical interactions. The high solubility of vinyl chloride in water, 0.6 wt %, accounts for a strong deviation from true emulsion behavior. Also, PVC's insolubility in its own monomer accounts for such behavior as a rate dependence on conversion. Emulsions of up to 0.2-μm dia are sold in liquid form for water-based paints, printing inks, and finishes for paper and fabric. Other versions, 0.3–10-μm dia and dried by spray-drying or coagulation, are used as plastisol resins.

Microsuspension Polymerization. Microsuspension polymerization uses a monomer-soluble initiator. The monomer is homogenized in water

along with emulsifiers or suspending agents to control the particle sizes. Microsuspension paste resins at 0.3–1-μm dia are used to make plastisols for flooring, seals, barriers, etc. These plastisols are also dispersions of PVC in liquid plasticizer and are cured by heating. Microsuspension blending resins at 10–100-μm dia are used as extenders to paste resins in plastisols.

Solution Polymerization. In solution polymerization, a solvent for the monomer is often used to obtain very uniform copolymers. Polymerization rates are normally slower than those for suspension or emulsion PVC.

Copolymerization. Vinyl chloride can be copolymerized with a variety of monomers. Vinyl acetate, the most important commercial comonomer, is used to reduce crystallinity, which aids fusion and allows lower processing temperatures. Copolymers are used in flooring and coatings. This copolymer sometimes contains maleic acid or vinyl alcohol (hydrolyzed from the poly(vinyl acetate)) to improve the coating's adhesion to other materials, including metals. Copolymers with vinylidene chloride are used as barrier films and coatings. Copolymers of vinyl chloride with acrylic esters in latex from are used as film formers in paint, nonwoven fabric binders, adhesives, and coatings. Copolymers with olefins improve thermal stability and melt flow, but at some loss of heat-deflection temperature.

Compounding

The additives found in PVC help make it one of the most versatile, cost-efficient materials in the world. Without additives, literally hundreds of commonly used PVC products would not exist. Many materials are useless until they undergo a similar modification process.

Stabilizers. Lead stabilizers, particularly tribasic lead sulfate, is commonly used in plasticized wire and cable compounds because of its good nonconducting electrical properties. Organotin stabilizers are commonly used for rigid PVC, including pipe, fittings, windows, siding profiles, packaging, and injection-molded parts.

Antimony tris(isooctylthioglycolate) has found use in pipe formulations at low levels. Barium–zinc stabilizers have found use in plasticized compounds, replacing barium–cadmium stabilizers. These are used in moldings, profiles, and wire coatings. Cadmium use has decreased because of environmental concerns surrounding certain heavy metals.

Calcium–zinc stabilizers are used in both plasticized PVC and rigid PVC for food contact where it is desired to minimize taste and odor characteristics. Applications include meat wrap, water bottles, and medical uses. Many stabilizers require costabilizers.

Impact Modifiers. Rubbery polymers are added to PVC to improve toughness. Rubbery particles are added to act as stress concentrators or multiple weak points, leading to crazing or shear-banding under impact load. This can result in cavitation and/or cold drawing, thus allowing the PVC to absorb large amounts of energy.

Processing Aids. PVC often flows in the form of billions of molecule primary particles. Processing aids glue these particles together before the PVC melts, thus acting as a fusion promoter. Processing aids also modify melt rheology by increasing melt elasticity and die swell; some by reducing melt viscosity and melt fracture.

Lubricants. A model for the lubrication mechanism has been developed that explains synergy between certain lubricants. This model treats lubricants as surface-active agents. Some lubricants have polar ends that are attracted to other polar ends and to polar PVC flow units and to polar metal surfaces. These also have nonpolar ends that are repelled by the polar groups. Synergy happens when nonpolar lubricants are added, which are attracted to the nonpolar ends and act as a slip layer.

Plasticizers. Solutions of PVC, prepared at elevated temperatures with high boiling solvents, possess unusual elastic properties when cooled to room temperature. Such solutions are flexible, elastic, and exhibit a high degree of chemical inertness and solvent resistance.

This unusual behavior results from unsolvated crystalline regions in the PVC that act as physical cross-links. These allow the PVC to accept large amounts of solvent (plasticizers) in the amorphous regions, lowering its T_g to well below room temperature, thus making it rubbery. PVC was, as a result, the first thermoplastic elastomer (TPE). This rubber-like material has stable properties over a wide temperature range.

Fillers. Fillers are used to improve strength and stiffness, to lower cost, and to control gloss. The most common filler is calcium carbonate.

Pigments. A variety of pigments are added to PVC to give color, including titanium dioxide and carbon black.

Ultraviolet Light Stabilizers. Both titanium dioxide and carbon black are strong ultraviolet light absorbers and effective in protecting the PVC. For ultraviolet light absorption in transparent PVC or for improvement of pigmented systems, various derivatives of benzotriazole are used.

Biocides. Although PVC itself and rigid PVC compounds are resistant to attack by microorganisms, plasticized PVC, in specific applications such as flashing and sealing boots on roofs, shower curtains, and swimming pools, may need protection. Many biocides, often containing arsenic compounds, are available for a balance of stability, compatibility, weatherability, and biocidal effectiveness.

Flame Retardants. Because PVC contains nearly half its weight of chlorine, it is inherently flame-retardant.

Foaming or Blowing Agents. Cellular PVC can be made by a variety of techniques, such as whipping air into a plastisol, incorporating a gas under pressure, incorporating a physical blowing agent into the melt, or using a chemical blowing agent which releases a gas when it decomposes with heat. The most common chemical blowing agent is 1, 1′-azobisdicarbonamide, which decomposes with heat to release nitrogen gas.

Uses

PVC is so versatile that it can be compounded for a wide range of properties and used in a wide variety of markets. Most of the products are durable goods and have long life spans. Its use in short-term, one-time-use products is limited.

Pipe and fittings, a principal market for PVC, are a prime example of PVC as an engineering thermoplastic.

PVC is accepted commercially as an excellent weathering material. PVC's chemical response to weathering is well understood so that compounds and products can be designed for satisfactory outdoor performance. Products include siding, windows, and doors.

Complex profiles require specialty manufacturing skills to build, maintain, and operate extrusion dies as well as cooling and sizing equipment to deliver the exact dimensions required. Cubed compound, where the PVC grains are already broken down, can be run faster on simple single-screw extruders on account of the typical low melt temperatures.

PVC has been used in wire and cable applications since World War II. The compounds are optimized for the requirements, including low temperature flexibility, high use temperature, especially low combustibility, weatherability, and high resistance to cutthrough.

Numerous housings, electrical enclosures, and cabinets are injection-molded from rigid PVC. These take advantage of PVC's outstanding UL flammability ratings and easy molding into thin-walled parts.

Health and Safety Factors

There are no significant health hazards arising from exposure to poly(vinyl chloride) at ambient temperature. At processing temperatures, most polymers emit fumes and vapors that may be irritating to the respiratory tract. Decomposition of plastics, e.g., through greatly elevated temperatures above normal operating temperatures, can result in personnel exposure to decomposition or combustion products. In the case of PVC compounds, such decomposition involves hydrogen chloride, which causes irritation of the respiratory tract, eyes, and skin.

Poly(vinyl chloride) resin has a flash point of approximately 391°C (735°F) and a self-ignition temperature of approximately 454°C (850°F) (ASTM D1929). In general, PVC burns with difficulty because a substantial amount of energy is required to break down the polymer. Poly(vinyl chloride) powder has a very low tendency to explode. In firefighting where PVC is involved, water, ABC dry chemical, or protein-type air foams should be sued as extinguishing media.

In the U.S., poly(vinyl chloride) is an EPA hazardous air pollutant under the Clean Air Act Section 112 (40 CFR 61) and is covered under the New Jersey Community Right-to-Know Survey: N.J. Environmental Hazardous Substances (EHS) List as "chloroethylene, polymer" with a reporting threshold of 225 kg (500 lb).

Environmental Considerations and Recycling

Over 30% of the chlorine produced on a global basis goes to make PVC. Chlorine makes PVC inherently flame-retardant. PVC is over 50% chlorine and, as a result, one of the most energy-efficient polymers. Chlorine makes PVC far more environmentally acceptable than other materials that are totally dependent on petrochemical feedstocks. In addition, recycling

PVC is easier because the chlorine in PVC acts as a marker, enabling automated equipment to sort PVC containers from other plastics in the waste stream.

Although vinyl is the world's second most widely used plastic, less than one-half percent by weight is found in the municipal solid waste stream. Most of that consists of vinyl packaging, bottles, blister packaging, and flexible film. This is because most vinyl applications are long-term uses, such as pipe and house siding, and are not disposed of quickly. Vinyl wastes are handled by all conventional disposal methods, i.e., recycling, landfilling, and incineration (including waste-to-energy).

A study sponsored by the American Society of Mechanical Engineers (ASME), involving the analysis of over 1700 test results from 155 large-scale, commercial incinerator facilities throughout the world, found no relationship between the chlorine content of waste and dioxin emissions from combustion processes. Instead, the study stated, the scientific literature is clear that the operating conditions of combustors are the critical factor in dioxin generation.

Incinerator scrubbing systems can remove about 99% of the hydrogen chloride generated by incinerating vinyl plastics and other chlorine-containing compounds and materials. Municipal incinerators are often targeted as a primary cause of acid rain. In fact, power plants burning fossil fuels, which produce sulfur dioxide and nitrogen oxide, are actually the leading cause of acid rain, along with automotive exhaust. In Europe and Japan, studies show that only about 0.02% of all acid rain can be traced to incineration of PVC.

Industrial scrap vinyl has been recycled for years, but in more recent years, post-consumer vinyl recycling is growing. In 1991, there were an estimated 1100 municipal recycling programs in place or planned in the United States that include vinyl.

In municipal recycling contamination occurs whether or not vinyl is present. Other resins are just as much a contamination problem as vinyl. Except for commingled plastics applications, different plastic materials cannot be mixed successfully in most recycled products applications. This is why it is crucial to separate efficiently one plastic from another.

It is not true that poly(ethylene terephthalate) (PET) and high density polyethylene (HDPE) packaging are listed as 1 and 2 in the Society of the Plastics Industry (SPI) recycling coding system because they are the most recyclable. The numbers assigned to each plastic in the SPI coding system are purely arbitrary and do not reflect the material's recyclability.

Vinyl plastics do not decompose in landfills and give off vinyl chloride monomer, because like all plastics, vinyl is an extremely stable landfill material. It resists chemical attack and degradation, and is so resistant to the conditions present in landfills that it is often used to make landfill liners. A recent study compared vinyl to a number of other packaging materials and found that vinyl consumed the least amount of energy, used the lowest level of fossil fuels, consumed the least amount of raw materials, and produced the lowest levels of carbon dioxide of any of the plastics studied.

It is not true that in a fire, vinyl is unusually hazardous and damaging. The real hazards in a fire are carbon monoxide and heat; these are especially a problem with other materials that readily burn. Because vinyl products contain chlorine, they are inherently flame-retardant and resist ignition. When it does burn, however, vinyl produces carbon monoxide, carbon dioxide, and hydrogen chloride. Of these, the most hazardous is carbon monoxide. Hydrogen chloride is an irritant gas that can be lethal at extremely high levels. However, research indicates that those levels are never reached or even approached in real fires.

VINYL ESTER RESINS. The vinyl ester resins are a relatively recent addition[1] to thermosetting-polymer-chemistry. Superficially, they are similar to unsaturated polyester resins insofar as they contain ethylmic unsaturation and are cured through a free-radical mechanism, usually in the presence of a vinyl monomer, such as styrene. However, close examination of the chemistry and structure of the vinyl ester resins demonstrates several basic differences which lead to their unique characteristics.

Vinyl ester resins are manufactured through an addition reaction of an epoxy resin with an acrylic monomer, such as acrylic acid, methacrylic acid, or the half-ester product of an hydroxyalkyl acrylate and anhydride. In contrast, the polyester resins are condensation products of dibasic acids and polyhydric alcohols. The relatively low-molecular-weight precise polymer structure of the vinyl ester resins is in contrast to the high-molecular-weight random structure of the polyesters.

Of particular importance in describing the difference between these two families of resins are the locations of the reactive unsaturation. In the polyester resin, these groups are located along the backbone of the polymer with terminal hydroxyl or carboxylic acid groups. The vinyl ester resins contain no significant acidity but terminate in reactive vinyl ester groups. Because of the location of these reactive sites, the vinyl ester resins will homopolymerize as well as coreact with various vinyl monomers.

Resin Properties

Vinyl esters, because of their relatively low molecular weight and precise structure, can be characterized as low-viscosity, fast-wetting, consistent-reactivity products. Typical property profiles for some uncured vinyl ester resins are given in Table 1. Properties of some cured resins are given in Table 2. Typically, 6-month stability can be expected at 25°C (77°F) with decreased storage life under elevated temperatures. In general, anyone familiar with the proper storage and handling of unsaturated polyester resins and styrene monomer experiences no difficulty with these materials.

Cure Mechanism

The free-radical cure mechanism of the vinyl ester resins is well understood. In most respects, it is similar to that of the unsaturated polyester resins. To initiate the curing process, it is necessary to generate free radicals within the resin mass. Organic peroxides are the most common source of free radicals. These peroxides will decompose under the influence of elevated temperatures or chemical promoters, e.g., organometallics or tertiary amines, to form free radicals. Generation of free radicals also can be effected by ultraviolet or high-energy radiation applied directly to the resin system. The free radicals thus formed react to open the double bond

of the vinyl group. Once opened, the resin vinyl group is highly reactive and rapidly combines with several more vinyl groups available from both the unreacted resin and the monomer. This exothermic reaction is rapidly carried to completion, forming a 3-dimensional thermosetting network.

Applications

As might be expected from the wide variation in resin properties that can be built into the molecule, the vinyl ester resins find many applications. Chief among these are fiberglass-reinforced plastics, where the inherent characteristics of the vinyl ester resin provide a cost and performance advantage over other materials. The largest application is in the manufacture of corrosion-resistant reinforced plastic structures. Because of the reduced number of ester groups within the resin structure, the corrosion-resistant vinyl ester resins are less prone to attack by hydrolysis than the bisphenol A-fumaric acid polyesters. In addition, the resilience of the vinyl ester resins (4–6% ultimate tensile elongation) results in a fabricated part which is less prone to damage during shipping, field erection, and service.

All fabrication methods commonly used in the manufacture of reinforced plastics can be used with the vinyl ester resins. In those applications, such as filament winding and bag molding, where fast wetting is important, significant increases in output can be realized. One technique to which vinyl ester resins are particularly suited is the use of sheet molding compound (SMC). Here, the resin system (usually with a high filler loading) is combined in sheet form with the glass reinforcement and chemically thickened through the use of metal oxides, such as MgO. The SMC then is molded, usually in a matched-die molding operation, to give the desired final product, e.g., automotive parts, appliance housings, electrical structures, and panel configurations. Vinyl ester resins diluted with vinyl toluene monomer are used in the production of high-temperature electrical laminating systems. See Structures (**1**) and (**2**).

Freeport, Texas

VINYL ETHER MONOMERS AND POLYMERS. Because of the strong electron-donating oxygen, the polymerization of vinyl ethers (VE) can be readily accomplished using cationic initiators, resulting in polymers and copolymers that have the potential for significant variety. However, only poly(methyl vinyl ether) (PMVE) achieved commercial success among the homopolymers, and its commercial importance has faded. Divinyl ethers are emerging as important ingredients in radiation-cured coatings, whereas copolymers of methyl vinyl ether (MVE) and maleic anhydride, easily prepared by free-radical initiation, continue to be valued as ingredients in personal care and pharmaceutical products.

Monomers

The most general commercial process for the manufacture of mono- and divinyl ethers, developed by Reppe in the 1930s at BASF, is by treating alcohols with acetylene under pressure of ≥6.8 atm (100 psi) at temperatures of 120–180°C in the presence of catalytic amounts of the corresponding metal alcoholate. The danger of handling acetylene under pressure in concentrated form requires sophisticated equipment and should only be attempted experimentally in an appropriately barricaded high pressure autoclave.

$$HC \equiv CH \xrightarrow{ROM} (ROCH = CHM) \xrightarrow{ROH} ROCH = CH_2 + ROM$$

Alternatively, thermal cracking of acetals or metal-catalyzed transvinylation can be employed. Some physical properties of the lower homologues of vinyl ether are presented in Table 1.

Reactions of Vinyl Ethers. Vinyl ethers undergo the typical reactions of activated carbon-carbon double bonds. A key reaction of VEs is acid-catalyzed hydrolysis to the corresponding alcohol and acetaldehyde, i.e., addition of water followed by decomposition of the hemiacetal. MVE is a reactive flammable gas and must be handled safely.

Homopolymerization

VEs such as MVE polymerize slowly in the presence of free-radical initiators to form low mol wt products of no commercial importance. Examples of anionic polymerization are unknown, whereas cationic initiation promotes rapid polymerization to high mol wt polymers in excellent yield and has been extensively studied.

A typical cationic polymerization is conducted with highly purified monomer free of moisture and residual alcohol, both of which act as inhibitors, in a suitably dry unreactive solvent such as toluene with a Friedel-Crafts catalyst, e.g., boron trifluoride, aluminum trichloride, and stannic chloride. Usually low temperatures (−40 to −70°C) are favored in order to prevent chain-transfer or side reactions.

The nature of the side chain R group exerts considerable influence on the reactivity of vinyl ethers toward cationic polymerization. The rate is fastest

TABLE 1. PHYSICAL PROPERTIES OF THE LOWER VINYL ETHERS

Property	Methyl	Ethyl	Isopropyl	*n*-Butyl	Isobutyl

[b] Tag open cup (ASTM D1310).

when the alkyl substituent is branched and electron-donating. Aromatic vinyl ethers are inherently less reactive and susceptible to side reactions.

Stereoregular Polymerization. In order to generate stereoregular (usually isotactic) polymers, the polymerization is conducted at low temperatures in nonpolar solvents. A variety of soluble initiators can produce isotactic polymers, but there are some initiators, e.g., $SnCl_4$, that produce atactic polymers under isotactic conditions. The nature of the pendant group can influence tacticity.

The low temperature limitation of homogeneous catalysis has been overcome with heterogeneous catalysts such as modified Ziegler-Natta solid-supported protonic acids and metal oxides.

It has been suggested that the mechanism of stereoregular vinyl ether polymerization heavily depends on the degree of association of the counterion with the growing terminal carbocation. An incoming monomer can approach the carbocation terminus from either the front-or back-side attack, which attack is prevalent depends on the tightness of the growing ion pair and the steric requirements of the particular vinyl ether monomer. Front-side attack is favored by a loose ion pair associated with polar solvents, whereas a back-side attack is favored by nonpolar solvents where a tight ion pair prevails.

Living Polymerization

Living polymerization is characterized by an increasing number-average molecular weight as the monomer is consumed. The rate of M_n increase is inversely proportional to the initial concentration of hydrogen iodide, not iodine, and the molecular weight distribution (MWD) of the polymer is very narrow throughout the course of the polymerization ($M_w/M_n < 1.1$). Thus, this type of polymerization can be stopped and started by consumption or addition of fresh monomer. It is similar to ethylene oxide/propylene oxide (EO/PO) anionic polymerization in this regard, but the initiation system is longer lived.

Living VE polymerization is usually terminated by addition of alcohols, phenols, amines, etc, that can replace iodide. Without some base present to neutralize generated HI, an aldehyde end group forms if moisture is present because of acid-catalyzed hydrolysis.

The living polymerization process offers enormous flexibility in the design of polymers. It is possible to control terminal functional groups, pendant groups, monomer sequencing along the main chain (including the order of addition and blockiness), steric structure, and spatial shape.

Homopolymer Properties

Physical properties, which depend on molecular weight, the nature of the alkyl group, the nature of the initiator, stereospecificity, and crystallinity, range from viscous liquids, through sticky liquids and rubbery solids, to brittle solids. Polyethers with long alkyl side chains are waxy, however, as the alkyl group in such cases dominates physical properties.

The glass-transition temperatures of the amorphous straight-chain alkyl vinyl ether homopolymers decrease with increasing length of the side chain. Also, the melting points of the semicrystalline poly(alkyl vinyl ether)s increase with increasing side-chain branching.

Commercial Aspects

No crystalline polymers are known to have been commercialized. This lack of commercial success results from the economically competitive situation concerning vinyl ether polymers versus other, more readily available polymers such as those based on acrylic and vinyl ester monomers.

Copolymerization

VEs do not readily enter into copolymerization by simple cationic polymerization techniques; instead, they can be mixed randomly or in blocks with the aid of living polymerization methods. Reactivity ratios must be taken into account if random copolymers, instead of mixtures of homopolymers, are to be obtained by standard cationic polymerization. VEs can also copolymerize by free-radical initiation with a variety of comonomers.

MVE/MAN Copolymers. Various mol wt grades of poly(methyl vinyl ether-*co*-maleic anhydride) (PMVEMA) are available. PMVEMA, supplied as a white, fluffy powder, is soluble in ketones, esters, pyridine, lactams, and aldehydes, and insoluble in aliphatic, aromatic, or halogenated hydrocarbons, as well as in ethyl ether and nitroparaffins. When the copolymer dissolves in water or alcohols, the anhydride group is cleaved, forming the polymers in free acid form or the half-esters of the corresponding alcohol, respectively.

International Specialty Products (ISP) supplies ethyl, isopropyl, and *n*-butyl half-esters of PMVEMA as 50% solutions in ethanol or 2-propanol. These half-esters do not dissolve in water but are soluble in dilute aqueous alkali and in aqueous alcoholic amine solutions. The main application for the half-esters is in hairsprays where they combine excellent hair-holding properties at high humidity without making the hair stiff or harsh. These half-esters are easily removed during shampooing, have a very low order of toxicity, and form tack-free films that exhibit good gloss, luster, and sheen (see **Enzyme Preparations**).

Health and Safety Factors

Poly(methyl vinyl ether-*co*-maleic anhydride) and their monoalkyl ester derivatives have been shown on rabbits to be neither primary irritants nor primary sensitizers to skin and eyes. The acute oral toxicities on white rats of the two copolymers are, respectively, 29 g/kg and 25 g/kg body weight.

Applications

Radiation-Curable Coatings. A wide variety of monovinyl and divinyl ethers are commercially available for this application, which allows the formulator greater latitude. For example, triethylene glycol divinyl ether (DVE-3) and 1,4-cyclohexanedimethanol divinyl ether (CHVE) can be combined as reactive diluents, with each contributing quite different properties to the subsequently cured coating. CHVE offers hard brittle films, whereas DVE-3 produces films that have greater flexibility.

Vinyl ethers can also be formulated with acrylic and unsaturated polyesters containing maleate or fumarate functionality. Because of their ability to form alternating copolymers by a free-radical polymerization mechanism, such formulations can be cured using free-radical photoinitiators. With acrylic monomers and oligomers, a hybrid approach has been taken using both simultaneous cationic and free-radical initiation.

Polymer-Polymer Compatibility. Frequently when polymers are mixed together they are immiscible because the combinatorial entropy of mixing is too small to overcome the enthalpy changes, which are usually positive. This small entropy of mixing is a result of the high mol wt nature of the component polymers. If the component polymers exhibit a specific interaction such as hydrogen bonding, Van der Waals, or electrostatic, etc, then miscibility can occur. In the case of PMVE–polystyrene, the blend presents a lower critical solution temperature (LCST) and the miscibility region depends on the molecular weight of the polymers. The interaction in this case is between the electrons of the ether groups and the aromatic polystyrene ring. In fact, PMVE can function as a diluent for isotactic polystyrene enhancing spherulite formation. Depending on the molecular weight and tacticity of the PMVE employed, separated regions of crystallized PMVE can function as reinforcement for polystyrene blends and offer improved plastic properties.

VINYLIDENE CHLORIDE MONOMER AND POLYMERS. Vinylidene chloride copolymers' most valuable property is low permeability to a wide range of gases and vapors. From the beginning in 1939, the word Saran has been used for polymers with high vinylidene chloride content, and it is still a trademark of The Dow Chemical Company in some countries. Sometimes Saran and poly(vinylidene chloride) are used interchangeably in the literature.

Three types of comonomers are commercially important: vinyl chloride; acrylates, including alkyl acrylates and alkylmethacrylates; and acrylonitrile. When extrusion is the method of fabrication, the formulation includes plasticizers, stabilizers, and extrusion aids.

Monomer

Properties. Pure vinylidene chloride (1,1-dichloroethylene) is a colorless, mobile liquid with a characteristic sweet odor. Its properties are summarized in Table 1. Vinylidene chloride is soluble in most polar and nonpolar organic solvents. Its solubility in water (0.25 wt %) is nearly independent of temperature at 16–90°C.

Manufacture. Vinylidene chloride monomer can be conveniently prepared in the laboratory by the reaction of 1,1,2-trichloroethane with aqueous alkali:

$$2\ CH_2ClCHCl_2 + Ca(OH)_2 \longrightarrow CH_2{=}CCl_2 + CaCl_2 + 2\ H_2O$$

Vinylidene chloride (VDC) is prepared commercially by the dehydrochlorination of 1,1,2-trichloroethane with lime or caustic in slight excess (2–10%). A continuous liquid-phase reaction at 98–99°C yields ~90% VDC. Commercial grades contain 200 ppm of the monomethyl ether of hydroquinone (MEHQ).

For many polymerizations, MEHQ need not be removed; instead, polymerization initiators are added. Vinylidene chloride from which the inhibitor has been removed should be refrigerated in the dark at −10°C, under a nitrogen atmosphere, and in a nickel-lined or baked phenolic-lined storage tank. If not used within one day, it should be reinhibited.

Health and Safety Factors. Vinylidene chloride is highly volatile and, when free of decomposition products, has a mild, sweet odor. A single, brief exposure to a high concentration of vinylidene chloride vapor, e.g., 2000 ppm, rapidly causes intoxication, which may progress to unconsciousness on prolonged exposure. Vinylidene chloride is hepatotoxic, but does not appear to be a carcinogen. The liquid is irritating to the skin after only a few minutes of contact. In the presence of air or oxygen, uninhibited vinylidene chloride forms a violently explosive complex peroxide at temperatures as low as 40°C. Vinylidene chloride containing peroxides may be purified by being washed several times, either with 10 wt % sodium hydroxide at 25°C or with a fresh 5 wt % sodium bisulfite solution.

Polymerization

Homopolymerization. The free-radical polymerization of VDC has been carried out by solution, slurry, suspension, and emulsion methods. Slurry polymerizations are usually used only in the laboratory. The heterogeneity of the reaction makes stirring and heat transfer difficult; consequently, these reactions cannot be easily controlled on a large scale. Aqueous emulsion or suspension reactions are preferred for large-scale operations. The spontaneous polymerization of VDC, so often observed when the monomer is stored at room temperature, is caused by peroxides formed from the reaction of VDC with oxygen. Very pure monomer does not polymerize under these conditions. Heterogeneous polymerization is characteristic of a number of monomers, including vinyl chloride and acrylonitrile.

Emulsion and suspension reactions are doubly heterogeneous; the polymer is insoluble in the monomer and both are insoluble in water.

The instability of PVDC is one of the reasons why ionic initiation of VDC polymerization has not been used extensively. Many of the common catalysts either react with the polymer or catalyze its degradation.

Copolymerization. The importance of VDC as a monomer results from its ability to copolymerize with other vinyl monomers. Bulk copolymerizations yielding high VDC-content copolymers are normally heterogeneous. During copolymerization, one monomer may add to the copolymer more rapidly than the other. Batch reactions carried to completion usually yield polymers of broad composition distribution. More often than not, this is an undesirable result.

Polymer Structure and Properties

The chemical composition of poly(vinylidene chloride) has been confirmed by various techniques, including elemental analysis, x-ray diffraction analysis, degradation studies, and ir, Raman, and nmr spectroscopy. The polymer chain is made up of vinylidene chloride units added head-to-tail:

$$-CH_2CCl_2-CH_2CCl_2-CH_2CCl_2-$$

Molecular weights of PVDC can be determined directly by dilute solution measurements in good solvents. Viscosity studies indicate that polymers having degrees of polymerization from 100 to more than 10,000 are easily obtained. Dimers and polymers having DP < 100 can be prepared by special procedures.

The crystal structure of PVDC is fairly well established. Several unit cells have been proposed. The unit cell contains four monomer units with two monomer units per repeat distance. The calculated density, 1.96 g/cm^3, is higher than the experimental values, which are 1.80–1.94 g/cm^3 at 25°C, depending on the sample. The melting temperature, T_m, of PVDC is independent of molecular weight above DP = 100. The properties of PVDC (Table 2) are usually modified by copolymerization.

TABLE 2. PROPERTIES OF POLY(VINYLIDENE CHLORIDE)

ΔH_m, J/mol[a]	6275	4600–7950

[a] To convert J to cal, divide by 4.184.

The highly crystalline particles of PVDC precipitated during polymerization are aggregates of thin lamellar crystals.

Melting temperatures of as-polymerized powders are high, i.e., 198–205°C. As-polymerized PVDC does not have a well-defined glass-transition temperature because of its high crystallinity. The amorphous polymer has a glass-transition temperature of −17°C. Once melted, PVDC does not regain its as-polymerized morphology when subsequently crystallized.

Poly(vinylidene chloride) does not dissolve in most common solvents at ambient temperatures. Copolymers, particularly those of low crystallinity, are much more soluble. However, one of the outstanding characteristics of vinylidene chloride polymers is resistance to a wide range of solvents and chemical reagents. The insolubility of PVDC results less from its polarity than from its high melting temperature. It dissolves readily in a wide variety of solvents above 130°C.

Poly(vinylidene chloride) also dissolves readily in certain solvent mixtures. One component must be a sulfoxide or *N,N*-dialkylamide. Effective cosolvents are less polar and have cyclic structures.

Mechanical Properties. Because PVDC is difficult to fabricate into suitable test specimens, very few direct measurements of its mechanical properties have been made. Some characteristic properties of high VDC content, unplasticized copolymers are listed in Table 3. The performance of a given specimen is sensitive to morphology, including the amount and kind of crystallinity, as well as orientation. Tensile strength increases with crystallinity, whereas toughness and elongation decrease. Orientation, however, improves all three properties.

In cases where the copolymers have substantially lower glasstransition temperatures, the modulus decreases with increasing comonomer content.

The long side chains of the acrylate ester group can apparently act as internal plasticizers. Substitution of a carboxyl group on the polymer chain increases brittleness. Copolymers of VDC with *N*-alkylacrylamides are more brittle than the corresponding acrylates even when the side chains are long.

Vinylidene chloride polymers are more impermeable to a wider variety of gases and liquids than other polymers. For example, commercial copolymers are available with oxygen permeabilities of 0.05 nmol/m·s·GPa. This is a consequence of the combination of high density and high crystallinity in the polymer. An increase in either tends to reduce permeability. Permeability is affected by the kind and amounts of comonomer as well as crystallinity. A more polar comonomer, e.g., an AN comonomer, increases the water-vapor transmission more than VC when other factors are constant. All VDC copolymers, are very impermeable to aliphatic hydrocarbons. Plasticizers increase permeability. However, water does not alter the permeability.

TABLE 3. MECHANICAL PROPERTIES OF HIGH VINYLIDENE CHLORIDE COPOLYMERS

[a] To convert MPa to psi, multiply by 145.
[b] To convert J/m to ft·lbf/in., divide by 53.38 (see ASTM D256).

Degradation Chemistry

Vinylidene chloride polymers are highly resistant to oxidation, permeation of small molecules, and biodegradation, which makes them extremely durable under most use conditions. However, these materials are thermally unstable and, when heated above about 120°C, undergo degradative dehydrochlorination.

The principal steps in the thermal degradation of VDC polymer are formation of a conjugated polyene sequence followed by carbonization.

On being heated, the polymer gradually changes color from yellow to brown and finally to black. In general, the stability of the polymer reflects the method of preparation, with bulk > solution > suspension ≫ emulsion.

To some extent, the stability of VDC polymers is dependent on the nature of the comonomer present. Copolymers with acrylates degrade slowly. Copolymers with acrylonitrile or methacrylate undergo degradation more readily.

The degradation of VDC polymers in nonpolar solvents is comparable to degradation in the solid state. However, these polymers are unstable in many polar solvent. The rate of dehydrochlorination increases markedly with solvent polarity. This reaction is clearly unlike thermal degradation and may well involve the generation of ionic species as intermediates.

Stabilization. The ideal stabilizer system should (*1*) absorb or combine with evolved hydrogen chloride irreversibly under conditions of use, but not strip hydrogen chloride from the polymer chain; (*2*) act as a selective uv absorber; (*3*) contain a reactive dienophilic moiety capable of preventing discoloration by reacting with and disrupting the color-producing conjugated polymer sequences; (*4*) possess nucleophilicity sufficient for reaction with allylic dichloromethylene units; (*5*) possess antioxidant activity so as to prevent the formation of carbonyl groups and other chlorine-labilizing structures; (*6*) be able to scavenge chlorine atoms and other free radicals efficiently; and (*7*) chelate metals, e.g., iron, to prevent chlorine coordination and the formation of metal chlorides.

Commercial Methods of Polymerization and Processing

Emulsion polymerization and suspension polymerization are the preferred industrial processes. Either process is carried out in a closed, stirred reactor, which should be glass-lined and jacketed for heating and cooling. The reactor must be purged of oxygen, and the water and monomer must be free of metallic impurities to prevent an adverse effect on the thermal stability of the polymer.

Emulsion polymerization is used commercially to make vinylidene chloride copolymers. The principal advantages are high molecular weight polymers can be produced in reasonable reaction times, especially copolymers with vinyl chloride and monomer can be added during the polymerization to maintain copolymer composition control. The disadvantages of emulsion polymerization result from the relatively high concentration of additives in the recipe. The water-soluble initiators, activators, and surface-active agents generally cause the polymer to have greater water sensitivity, poorer electrical properties, and poorer heat and light stability.

Suspension polymerization of vinylidene chloride is used commercially to make molding and extrusion resins. The principal advantage is the use of fewer ingredients that might detract from the polymer properties. Stability is improved and water sensitivity is decreased. Extended reaction times and the difficult preparation of higher molecular weight polymers are disadvantages of the suspension process compared to the emulsion process, particularly for copolymers containing vinyl chloride.

The batch-suspension process does not compensate for composition drift, whereas constant-composition processes have been designed for emulsion or suspension reactions. It is more difficult to design controlled-composition processes by suspension methods.

Applications

Vinylidene chloride–vinyl chloride copolymers were originally developed for thermoplastic molding applications, and small amounts are still used for this purpose. Extrusion of VDC–VC copolymers is the main fabrication technique for filaments, films, rods, and tubing or pipe, and involves the same concerns for thermal degradation, streamlined flow, and noncatalytic materials of construction as described for injection-molding resins. A significant application for vinylidene chloride copolymer resins is in the

construction of multilayer film and sheet. This permits the design of a packaging material with a combination of properties not obtainable in any single material. Rigid containers for food packaging can be made from coextruded sheet that contains a layer of a barrier polymer.

Vinylidene chloride polymers have several properties that are valuable in the coatings industry: excellent resistance to gas and moisture vapor transmission, good resistance to attack by solvents and by fats and oils, high strength, and the ability to be heat-sealed.

Vinylidene chloride polymers are often made in emulsion, but usually are isolated, dried, and used as conventional resins. Stable latices have been prepared and can be used directly for coatings. The principal applications for these materials are as barrier coatings on paper products and, more recently, on plastic films.

Vinylidene chloride emulsion copolymers are used in a variety of ignition-resistant binding applications.

VIRTANEN, ARRTURI I. (1895–1973). A Finnish biochemist that won the Nobel prize in 1945. His work was primarily concerned with research in nutrition and agriculture. He made important discoveries regarding prevention of fodder spoilage and bacterial fermentation as well as nitrogen metabolism in plants. His Ph.D. was awarded at the University of Helsinki and followed by an illustrious career that included awards throughout Scandanavia.

VIRUS. Viruses are considered to be the smallest infectious agents capable of replicating themselves inside eukaryotic or prokaryotic cells. The majority of these extremely small infectious particles fall within a size range of about 0.02–0.25 micrometer and can only be visualized directly with the aid of an electron microscope.

In 1898, Loeffler and Frosch demonstrated that foot-and-mouth disease of cattle could be transferred by material passed through a filter capable of excluding bacteria. This new group of "organisms" subsequently became known as *filterable viruses*. Years of debate have centered around the question of whether viruses are living or nonliving and, although resolution of this is now considered to be simply a problem of semantics, several fundamental differences distinguish viruses from other organisms. Viruses, unlike true microorganisms, are not cells, do not replicate by binary fission, and contain a genome consisting of only one type of nucleic acid (DNA or RNA, double or single stranded). They contain no organelles, such as mitochondria or ribosomes (except for the Arena viruses, which contain cellular ribosomes). Some virions contain special enzymes, such as transcriptase required for initiation of the vital growth cycle, not present in host cells.

Smaller than viruses, however, are the particles known as *viroids*, which are nothing more than very short strands of RNA uncoated by protein as is a normal virus. Viroids are known to be responsible for several plant diseases and may also be involved in animal and rare human nerve diseases. Very little is known about viroids except that when they are introduced into a host cell they replicate without the assistance of a helper virus. They are not translated into proteins and, presumably, their replication must rely entirely upon the enzyme systems of the host.

Viruses are obligatory intracellular parasites and, as such, cannot replicate in cell-free media. Therefore, the study of viruses is normally carried out with cultured cells. These are classified as: (1) *Primary cell cultures*; (2) *diploid cell strains*; and (3) *continuous cell lines*. Primary cell cultures are developed on tissue freshly removed from a plant or animal, contain several cell types capable of supporting replication of a wide range of viruses, but are limited to only a few cycles of cell division *in vitro*. Diploid cell strains contain cells of a single type which retain their original diploid chromosome number and are capable of up to about 100 divisions *in vitro*. Continuous cell lines consist of transformed or dedifferentiated cells of a single type which bear little resemblance to normal cells of that type. Continuous cell lines are capable of indefinite propagation *in vitro*.

Viral Structure. The mature virus particle, referred to as the *virion*, consists of a nucleic acid molecule(s) surrounded by a protein coat, the *capsid*. The capsid is composed of a number of *capsomeres* comprising one or more polypeptide chains and in some viruses surrounds a protein *core*. The capsid and enclosed nucleic acid together constitute the *nucleocapsid*. The viral capsid symmetry is characteristic of groups of virus and may be icosahedral (cubic) or helical. The icosahedron has 12 vertices and 20 faces, each an equilateral triangle. Nucleocapsids exhibiting helical symmetry consist of capsomeres and nucleic acid wound together into a spiral or helix. However, regardless of capsid symmetry, the actual virion may appear to be round, brick, or bullet-shaped. Some icosahedral and all helical viruses are enclosed in an outer *envelope* composed of lipoprotein, which is derived directly from the virus-modified cellular membrane during release of the nucleocapsid from the infected cell by a process called *budding*. Enveloped viruses can usually be inactivated by ether, chloroform, or bile salts.

Nucleic acid extracted from purified virus using phenol or dodecyl sulfate is easily destroyed by the homologous nucleases present in normal sera or tissues. DNA is destroyed by the enzyme deoxyribonuclease; RNA by ribonucleases. This provides one means of identifying the type of nucleic acid. The intact virus is not affected by these enzymes.

Bacteriophage, a virus infecting bacterial cells, has a structure somewhat different from those previously described. A *head* contains the nucleic acid and the viral DNA passes through a *tail* during the infection process. In the T-even phages (Fig. 1), the tail consists of a tube surrounded by a *sheath* and is connected to a thin *collar* at the head end and a plate at the tip end. The sheath is capable of contraction and the plate possesses *pins* and *tail fibers*, which are the organs of attachment of the bacteriophage to the wall of the host cell.

Some strains of the bacterium *Escherichia coli* harbor a dormant virus called lambda, which consists of a long molecule of DNA enclosed in protein. Exposure of such infected bacteria to ultraviolet light suddenly "switches on" these inactive lambda. The viruses proliferate and some 45 minutes after irradiation the bacteria burst, yielding a crop of new virus particles. If the bacteria are not irradiated, they grow normally, and rarely give rise spontaneously to viruses.

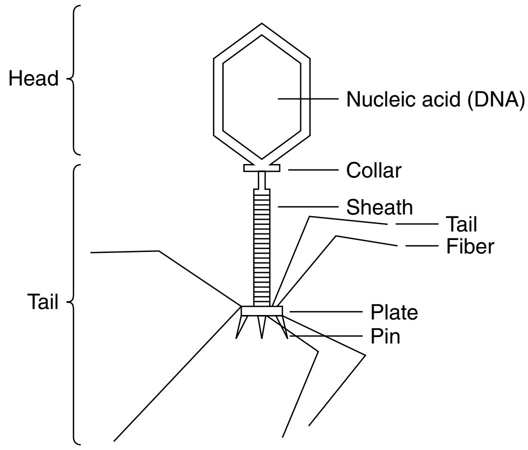

Fig. 1. T-even bacteriophage

Viral Replication. In contrast to eukaryotic and prokaryotic cells, which multiply by binary fission, viruses multiply by synthesis of their separate components, followed by assembly. Several stages are involved in viral replication:

(1) *Attachment or adsorption*. The virus becomes attached to the cell via specific receptors. Thus, cells lacking the receptors are resistant to attack.

(2) *Penetration*. With enveloped viruses, this step occurs when the virion's envelope fuses with the cellular membrane. Naked virions penetrate intact through the cellular plasma membrane and into the cell cytoplasm. Viruses may also enter the cell by cellular phagocytosis. Ordinarily, without a protein coat, viral nucleic acid is incapable of entering a cell, showing the importance of the coat in infectivity. The efficiency of infection with naked nucleic acid can be increased by the presence of basic polymers, such as DEAE-dextran, or by pretreating cells with hypertonic salt solution. Even under the most favorable conditions, however, the efficiency of infection is not more than 1% that of the corresponding intact virions.

(3) *Uncoating and eclipse*. Uncoating is detected by the lability of viral nucleic acids to nuclease after the artificial disruption of the cell. Eclipse is recognized by loss of infectivity of intracellular virions recovered from disrupted cells.

Once inside the cell, virulent viruses turn off cellular macromolecular synthesis and disaggregate cellular polyribosomes, thus favoring a shift to viral synthesis. These viruses cause the ultimate destruction of the infected cell. In contrast, moderate viruses may stimulate host DNA, mRNA, and protein synthesis—a phenomenon which may be of considerable importance in viral carcinogenesis.

In general, the DNA viruses multiply in the nucleus of the host cell. The viral DNA is transcribed in the nucleus and the resultant mRNA translated into proteins on cytoplasmic ribosomes. Depending upon the virus type, "early" or "late" proteins may be synthesized. These proteins may function as enzymes in replication of the viral DNA, as structural components of progeny virions, or as regulatory proteins. Replication of the viral DNA is semiconservative and, in general, depends upon viral proteins.

RNA viruses usually replicate in the cytoplasm and can be divided into five classes according to the nature of the RNA in the virion. *Class I* viruses contain a molecule of single-stranded RNA which acts as mRNA to be translated into viral proteins. The RNA is said to have plus *strand polarity*. The picornaviruses are an example. *Class II* viruses (e.g., paramyxoviruses) have a molecule of single-stranded RNA which cannot act as mRNA (minus strand polarity). A virion transcriptase synthesizes several complementary messenger molecules from which viral proteins are translated. *Class III* viruses (e.g., myxoviruses) contain single-stranded RNA of minus strand polarity, present in seven or more segments. A virion transcriptase transcribes each segment into a complementary messenger. *Class IV* viruses contain ten segments of double-stranded RNA which is transcribed into mRNA by a viral transcriptase. Representative of this group are the reoviruses. *Class V* viruses (e.g., leukoviruses) contain segmented single-stranded RNA of messenger polarity. Each RNA segment is transcribed into DNA by a *reverse transcriptase* present in the virion; mRNA is then transcribed from the DNA.

(4) *Assembly and release*. The assembly of the capsid and its association with nucleic acid is then followed by release of the virus from the cell. This may occur in different ways, depending upon the nature of the virus. Naked viruses may be released slowly and extruded without cell lysis, or released rapidly by disruption of the cell membrane. DNA viruses, which mature in the nucleus, tend to accumulate within infected cells over a long period. Enveloped viruses generally acquire their envelope and leave the cell by budding through the nuclear or cytoplasmic membrane at a point where virus-specified proteins have been inserted. The budding process is compatible with cell survival.

Viral Classification

Several methods of viral classification are in use. Classification based upon epidemiological criteria, such as enteric or respiratory viruses, is useful, but of more significance are schemes based upon the morphology of the virion (symmetry, envelope, etc.) and type of nucleic acid (DNA, RNA, number of strands, polarity, etc.).

The two groups of viruses, RNA and DNA, are further divided according to size, morphology, and biological and chemical properties. Thus, the icosahedral RNA viruses that are ether stable are divided into the picornaviruses and the reoviruses. The name picornavirus comes from *pico* (meaning very small) and *rna* (indicating the type of nucleic acid). Included in the group are enteroviruses, such as polio, Coxsackie, foot-and-mouth, and echoviruses, among others, and also the rhinoviruses. The picornavirus capsid consists of 60 subunits each made up of four proteins, which change by mutation to yield antibody-resistant strains of cold and polio viruses. The reoviruses (*r*espiratory *e*nteric *o*rphan virus) cause inapparent infection in humans and other animals, and their relationship to spontaneous disease is uncertain. They are morphologically similar to the wound-tumor virus of clover, and a small cross-activity with this virus by means of complement fixation has been reported.

The arboviruses are those which multiply in both vertebrates and arthropods. The former serve as reservoirs and the latter primarily as vectors. Arbovirus is a somewhat arbitrary epidemiological classification, which contains several heterogeneous groups. The togaviruses contain such entities as Eastern and Western equine encephalitis viruses (EEE and WEE) and dengue and yellow fever viruses, which have mosquitoes as vectors. The arenaviruses comprise such agents as Lassa, Tacaribe, and lymphocytic choriomeningitis viruses. Arboviruses are dangerous and difficult to study. They appear to contain single-stranded RNA (positive polarity), are ether sensitive, and are relatively unstable. The capsids are suggestive of icosahedral symmetry.

Myxoviruses, orthomyxovirus, and paramyxoviruses are spherical or filamentous, enveloped single-stranded RNA viruses. The myxovirus group contains the influenza viruses which, in turn, have been separated into three distinct antigenic types, designated A, B, and C. The genome of myxoviruses, unlike that of the paramyxoviruses, is segmented. It is this characteristic that is responsible for the devastating influenza pandemics which have occurred periodically. Influenza A viruses have undergone three major antigenic shifts since 1933, and each new variant is able to successfully infect populations of individuals immune only to preexisting types. In the influenza pandemic of the winter of 1917–1918, over 20 million persons died worldwide, with better than one-half million fatal cases in the United States. Over 50 million cases of influenza were reported in the United States in the 1968–1969 winter. These cases were attributed to a hitherto unknown variant, first isolated in Hong Kong (hence named "Hong Kong flu"). Some 20,000 and possibly as many as 80,000 deaths resulted from this influenza invasion and the side effects it produced. In the 1972–1973 winter season, a much milder and minor variant, called the "London flu," caused well over 2000 deaths in the United States, particularly from complications such as pneumonia. When combined with influenza, pneumonia is the fifth most serious public health problem in the United States. In terms of absenteeism, it is the number one problem.

Only Type A influenza virus has been found to be capable of producing *pandemics*. The influenza A virus is identified as a medium-size RNA virus, some 110 nanometers in diameter and delimited by a membrane of lipids and polysaccharides derived from the host cell and virus-specific protein. Five distinct proteins have been identified, three of which are inside the virion. A schematic representation of the influenza virus emerging from a cell is given in Fig. 2.

It has been reported that the antigenic shifts are manifested in hemagglutinin and neuraminidase, two glycoproteins found on the surface of the influenza virion. It is suggested that the hemagglutinin binds the virus to t he target cell and when the hemagglutinin function is inhibited

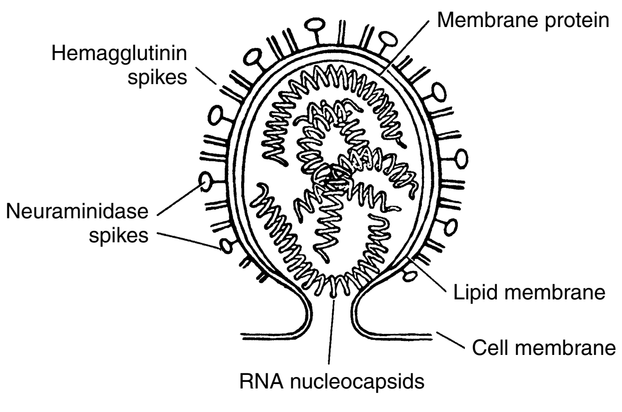

Fig. 2. Schematic representation of an influenza virus emerging from a cell. (*After Kilbourne*)

(as by an antibody), the virus is no longer infective. It is believed that the neuraminidase cleaves a glycoside bond in the host membrane. This action frees the newly formed virus from the cell and, if inhibited, will not reduce the infectivity of the virus, but will deter the spread of virus particles to other cells.

The emergence of new influenza subtypes appears to be too abrupt to be explained fully by conventional concepts of mutation and the full story may rest in the very nature of the segmented viral genome. If a host cell is infected by two different subtypes of influenza virus at the same time, the genes from the subtype may undergo random reassortment in the cell, resulting not only in production of the two original subtypes, but in production of one or several other subtypes as well. Each hybrid, of course, will have a different but full set of genes and recombination within the infected host can explain the large mutations that occur about once every decade. However, it is well established that only one influenza subtype can exist in humans at any given time. Also, that the emergence of a new subtype, such as the Hong Kong strain, is usually accompanied by the abrupt disappearance of the antecedent subtypes—thus allowing little, if any, opportunity for recombinations to occur within human cells. Of considerable interest, however, is the fact that several virus strains can exist simultaneously within animal hosts. In animals, the appearance of a new influenza virus strain is not necessarily accompanied by the disappearance of previously recognized strains. It has been established that there are at least two discrete subtypes of equine influenza, eight or more avian strains and two subtypes in swine. Thus, the postulation that recombination occurs in animals which share the general environs with humans. Some evidence of this may derive from the fact that most new subtypes appear to originate in Asia, where animals and humans commonly inhabit the same building.

The paramyxovirus group includes the causative viruses of mumps, measles, parainfluenza, Newcastle disease, canine distemper, and several other diseases. These viruses are generally larger than the myxoviruses, are enveloped and pleomorphic, and contain one molecule of single-stranded RNA.

The rhabdoviruses, causative agents of rabies in humans and other animals, are also enveloped and contain a single strand of RNA. A peculiar bullet-shaped morphology disguises the helical nucleocapsid.

The human immunodeficiency virus (HIV) which induces AIDS is a retrovirus. Its genetic material is RNA and it carries with it a reverse transcriptase which catalyzes transcription of viral RNA into double helical DNA that then integrates into the genome of the infected cell where it is known as a *provirus*. Transcription of this provirus produces new viral RNA and proteins. One characteristic of HIV is that its genome is significantly more complex than that of other known retroviruses; it possesses at least seven types of genes instead of the normal three. The virus replicates by budding off from a T lymphocyte to become a free infectious virus. See also **Immune System and Immunochemistry**.

The chemical nature of many viruses, which either do not grow well or do not lend themselves to purification, is unknown. The Riley lactic dehydrogenase virus is a nonpathogenic virus, which is recognized only by an increase in lactic dehydrogenase in the blood of infected mice. A lipovirus described by Chang causes marked degradation of infected cells and releases a lipogenic toxin dissociable from infectivity, which is capable of inducing fatty degeneration in other uninfected cells. A marked increase in the gamma globulin fraction of blood serum of mink infected with Aleutian mink disease is an indication of infection with a virus which causes a color change in the fur and often sickness and death.

Several groups of viruses, of importance in human disease, contain DNA. The adenoviruses, named for their original isolation from adenoid tissue, contain double-stranded DNA, have icosahedral symmetry and lack and envelope. This group of viruses that multiply in the nucleus of infected cells is usually associated with respiratory tract and eye infections, although it is now apparent that adenoviruses are not the etiological agents for the majority of acute viral respiratory infections. Although adenoviruses exhibit marked oncogenic (tumor causing) potential in animals, they are probably not oncogenic for humans.

The adenoviruses contain at least three protein moieties, and certain types are capable of inducing one or more new host antigens, such as tumor (T) antigens, the chemistry of which is presently unknown. The viral proteins can be separated by gel diffusion and correlated with results obtained by complement fixation. One moiety is the toxic protein that causes the host cell to degenerate. Another corresponds to the group antigen common to all 31 types of adenoviruses and the third is the type-specific protein.

The papovaviruses (*pap*-illoma, *po*-lyoma, *va*-cuolating agent, SV40) are small, nonenveloped, icosahedral viruses which also replicate in the cell nucleus. The virion contains double-stranded DNA. Apart from causing several forms of warts, this group of viruses is of interest as models for understanding mechanisms of viral carcinogenesis.

The major herpesviruses (Gr: *herpein* = to creep) that infect humans are herpes simplex (Type I: fever blisters; Type II: genital lesions), varicella (chickenpox), zoster (shingles), cytomegalovirus, and Epstein-Bar viruses. A number of viruses that infect lower animals also belong to this group of enveloped, icosahedral, double-stranded DNA viruses. Most members of this group tend to produce latent infections with periodic recurrent disease. Two examples are fever blisters caused by herpes simplex I, and shingles, the recurrent form of chickenpox. Cytomegalovirus causes a severe, often fatal, illness of newborns, usually affecting the salivary glands, brain, lungs, kidneys, and liver. Surpassing rubella virus, this is the most common viral cause of mental retardation. It has been estimated that cytomegalovirus (CMV) causes serious mental retardation of more than 3000 infants annually in the United States alone. In addition to mental retardation, the disease in infants may cause blindness and deafness. In about 90% of infants infected with CMV, the disease can be detected only through urine examination. In about 10% of the cases, the disease is typified by enlargement of the spleen and liver, blood abnormalities, and hepatitis. Microcephaly (abnormally small head) is also sometimes an indication. CMV causes enlargement of the affected cells (cytomegaly). The disease is found throughout the world and it is believed that congenital infections result from a primary infection of the mother during pregnancy. CMV, like herpesviruses, probably persist in a latent stage for long spans of time. Immunosuppressed patients, such as those suffering from cancer or recipients of organ transplants, are also prone to infections with CMV.

The Epstein-Barr viruses play an etiological role in infectious mononucleosis, an acute infectious disease that affects lymphoid tissue throughout the body. A strong association of this virus with Burkitt's lymphoma and perhaps nasopharyngeal carcinoma also has been observed.

The poxviruses are the largest and most complex viruses of vertebrates and contain a large, double-stranded DNA molecule. The virions are complex, brick-shaped particles, covered by several membrane layers of viral origin. Unlike other DNA viruses of mammals, poxviruses multiply in the cell cytoplasm. They can be divided into several groups on the basis of specific antigens, morphology, and natural hosts. *Group I* consists of mammalian viruses, such as variola (smallpox), vaccinia, cowpox, ectromelia, and monkeypox. Of this group, variola or smallpox has caused the greatest human morbidity and mortality. However, because the virus has no animal reservoir, and is spread chiefly by human contact, the World Health Organization was able to announce in 1980 that, because of massive immunization campaigns, smallpox has been completely eradicated. Since that announcement, remaining stores of the virus have been destroyed to prevent laboratory accidents, such as the one in 1979, which took the life of a scientist. *Group II* comprises the tumor-producing viruses, the fibroma and myxoma viruses.

The hepatitic viruses appear to fall into two different groups of small, icosahedral DNA viruses. *Type A* causes infectious hepatitis and is transmitted through the oral-intestinal route. *Type B* is transmitted by injection, usually of infected blood or its products.

Slow Viruses

During the last decade or two, there has been increasing speculation and some tentative evidence that so-called *slow viruses* may be operative and may be the underlying causes of a number of degenerative diseases, long poorly understood, such as multiple sclerosis and rheumatoid arthritis, among others. More recently, there have been increasing postulations of an association between viruses and diabetes. In fact, rather positive identification of slow viruses with some rare diseases has been established. Most investigators caution that the term "slow" should not necessarily be fully interpreted in terms of a virus per se, but equally if not completely with the manifestations of the virus. So-called slow virus infections are characterized by a long incubation period, followed by a protracted course of disease. The slowness may arise in some cases from the virus itself, but the slow pace also may be the result of weak but prolonged interactions between the virus and the host's immune system. It is also possible that these characterizations of slowness may not be attributable to viruses at all, but to some other unknown causative factors. Obviously as of this juncture, investigators are following a source of suspicion rather than a

chain of hard evidence. Nevertheless, the case for the slow viruses is becoming increasingly convincing. The causative agents for at least four rare diseases, two in humans and two in animals, are sometimes referred to as "unconventional viruses."

One of these diseases in humans is *kuru*, encountered only in the Fore people and their neighbors in New Guinea. The disease for many years was considered a genetic disease. However, it has been established that the disease can be transmitted to chimpanzees by injection of extracts from the brains of human kuru victims into the brains of chimpanzees. Kuru is a neurological disease with brain lesions located mainly in the gray matter. The cerebral cortex takes on a spongy appearance. The other human disease is Creutzfeld-Jakob disease, rare but of worldwide distribution. It involves the premature development of the mental deterioration sometimes seen in old age. It also has been established that it is caused by a transmissible agent that can infect chimpanzees and lower primates. One of the animal diseases referred to is *scapie*, known for over two centuries as a fatal disease among sheep. The other animal disease is *transmissible mink encephalopathy*, first discovered in Wisconsin in the late 1940s. A puzzling aspect of the unconventional slow viruses is the fact that they cannot be observed with an electron microscope. Another puzzling aspect is their apparent lack of antigenicity. Although it has not been possible to demonstrate that any of these four "agents" will evoke production of antibodies, recent work has found fibrils in the brains of infected animals that are believed to be specific markers for the "unconventional" slow viruses and may indeed be the etiological agent. These unconventional slow viruses are not destroyed by ultraviolet radiation, and they are highly resistant to treatment with formalin or heat, but infectivity is destroyed by phenol or ether. Some investigators believe that these agents may incorporate a very small nucleus of the size range of the viroids (self-replicating infectious RNA molecules known to produce certain plant diseases).

Two slow infections of the human central nervous system—*progressive multifocal leukoencephalopathy* (PML) and *subacute sclerosing panencephalitis* (SSPE) are thought to be associated with conventional viruses. Although PML does not cause inflammation of the brain, it does produce demyelination, i.e., destruction of the layers of membranes surrounding nerve axons. Some investigators believe that the virus is a papovavirus (group of small viruses including human wart virus, simian virus 40, and the polyoma virus of mice). It is reasoned that in PML the virus destroys the cells needed for formation and maintenance of the myelin sheath. A conventional virus has been isolated from the brains of persons suffering from SSPE. An association between measles (in patients under two years of age) or immunization with a live measles virus vaccine and later development of SSPE has been shown. SSPE patients have unusually high titres of measles antibodies and affected brain cells have inclusions similar to those seen in measles infections.

Slow viruses are becoming increasingly suspect in the instances of much more common diseases, particularly the autoimmune diseases. An autoimmune disease may be defined as a disease wherein the immune system of the body does not direct its attack on an invading foreign substance, but instead at the body's own tissue. Many authorities consider rheumatoid arthritis and multiple sclerosis as autoimmune diseases. The precise causes of these diseases have remained obscure. Multiple sclerosis is a demyelinating disease and has variously been described as an autoimmune disease, a viral disease, or an autoimmune disease provoked by a virus. Epidemiological studies indicate that from 3 to 23 years may elapse between the time of exposure to the virus and the onset of symptoms. Further evidence points to involvement of a myxovirus. Measles virus is of this kind.

Possible Viral Connection to Diabetes. A Norwegian physician (J. Stang) in 1864 noted that diabetes developed in one of his patients within a short period after a mumps infection and was probably the first person to indicate a possible connection between viruses and diabetes. Over the years, numerous other connections have been attempted to relate diabetes with mumps, hepatitis, rubella, coxsackie, and influenza viruses, adenoviruses, enteroviruses, and cytomegalovirus. One of the presumptions made is that viruses are understood to replicate in the pancreas. Commencing in the late 1950s, more substantive evidence has been given. Reports from Sweden in 1958 link juvenile diabetes with mumps infection. Reports from New York State in 1974 relate closely the cycles of incidence of mumps and those of juvenile diabetes. The study was based upon investigation of records for the period 1946–1971. Tentative conclusions indicate an average lag period of about 3.8 years between onset of diabetes and exposure to mumps and it is reasoned that this represents the time required for the virus to produce permanent damage to the pancreas. Other investigators have statistically linked diabetes to rubella (German measles). Some authorities suggest that the pancreas, along with other embryonic organs, may be damaged by the virus that causes congenital rubella. The records of nearly 3,000 juvenile diabetics treated at King's College Hospital in London (1955–1968) have been studied, and they reveal a seasonal pattern on the onset of juvenile diabetes, striking a low incidence in June and a high incidence in October. Without presenting the details, conclusions are suggested that an association of viral infections with the juvenile form of diabetes is evident. However, the relationship, if any, has not been determined in the case of the maturity-onset form of diabetes.

Viral Diagnosis and Vaccination

Viral Diagnosis. Three major approaches to identification of viruses are commonly used: (1) *Microscopy*. Viruses may be observed directly by electron microscopy; viral antigens may be recognized in infected tissue by immunofluorescence, using virus-specific antisera; virus-induced pathology may be identified by light microscopy. (2) *Virus isolation*. Provisional viral identification may be based upon cytopathic effects produced in cell cultures infected with virus present in tissues or secretions of the patient. (3) *Serology*. Antibodies specific for a particular virus may be identified in a patient's serum. A very sensitive, accurate, and recently developed diagnostic approach is radioimmunoassay, which involves the use of an isotope-labelled antibody or antigen.

Viral Vaccination. Vaccines, agents that elicit a specific antiviral immune response, have been very successful against smallpox, measles, rubella, poliomyelitis, and yellow fever, all of which are generalized diseases. Vaccines against diseases caused by respiratory tract viruses, where great antigenic diversity is found, have been less effective.

Vaccines may be prepared by rendering viruses harmless without affecting their immunogenicity. This can be done by either inactivating the virus, or by selecting avirulent mutants. The most successful vaccines are "living" avirulent viruses, which possess the advantage of multiplying in the host and which usually require only a single dose to be effective. This leads to prolonged immunological stimulation similar to that which occurs in natural infection. Live vaccines, however, are subject to a number of problems, such as genetic instability and contamination by extraneous viruses. Inactivated viruses are usually produced by treatment with formaldehyde, which destroys their infectivity. The major difficulty with inactivated viruses is the administration of sufficient viral antigen to induce a lasting immunity. In many cases, several injections must be given over a substantial period of time. The only inactivated viral vaccine in widespread use in humans is the influenza vaccine. The inactivated Salk polio vaccine has been largely replaced by the attenuated live-virus Sabin vaccine.

Interferon. Interferons (IFN) are proteins that evert virus nonspecific antiviral activities in cells through metabolic processes involving synthesis of both DNA and protein. The number of interferon-inducing substances has increased to include not only all of the major virus groups, but also bacterial and fungal products, nucleic acids, polymers, mitogens, and various low-molecular-weight substances. However, as interferons are induced by viruses and inhibit viral replication, viruses are usually considered to be natural inducers. The ability of viruses to induce interferon production depends upon the virus type. Some viruses, such as that responsible for Newcastle disease, are good inducers, while others, such as the adenoviruses, are regarded as poor inducers. Further, the type of cell used presents another factor in interferon production. In the whole animal, cells of the reticuloendothelial system are generally considered to be the major interferon producers. Recently, interferons have been classified into types on the basis of their antigenic specificities. Alpha and beta interferons (formerly called leukocyte and fibroblast, respectively) are acid stable and correspond to what have been called *Type I* IFNs (interferons). Gamma interferons (formerly called Immune) are acid labile and correspond to *Type II* IFNs.

Although interferon has been studied extensively for over a decade, the mechanism of its antiviral activity remains unclear. Considerable evidence exists to support the concept that interferon inhibits virus-specific protein synthesis, thus blocking viral replication in cells adjacent to the infected cell producing the interferon. There is no established reason to conclude, however, that interferon exerts antiviral action through a single mechanism.

Interferon is probably one of the most important early determinants of recovery from a number of viral diseases.

Recent work has centered upon use of interferon as a therapeutic agent in humans and animals. In humans, local application of monkey interferon is effective in reducing the severity of vaccinia virus skin infections. Recent results with herpes keratitis and chronic hepatitis are promising. Interferon appears to be active against oncogenic viruses in the treatment of such cancers as osteogenic sarcoma, and at present it is only the limited availability of interferon that prevents more extensive testing.

A number of virus diseases and virus related topics are described in this encyclopedia. Check alphabetical index for antiviral drugs, cancer research, chickenpox, common cold; coxsackie virus, dengue (breakbone fever), hepatitis, infectious mononucleosis, influenza, measles, mumps, Norwalk virus, poliomyelitis, rabies, Rift Valley fever, vaccinia, virus diseases (plants), and yellow fever.

VISCOELASTICITY. Mechanical behavior of material which exhibits viscous and delayed elastic response to stress in addition to instantaneous elasticity. Such properties can be considered to be associated with rate effects—time derivatives of arbitrary order of both stress and strain appearing in the constitutive equation—or hereditary or memory influences which include the history of the stress and strain variation from the undisturbed state. See also **Rheology**.

VISCOMETER (or Viscosimeter). A device for measuring the viscosity of a liquid. The types most widely used are the Engler, Saybolt, and Redwood, which indicate viscosity by the rate of flow of the test liquid through an orifice of standard diameter of the flow rate of a metal ball through a column of the liquid. Other types utilize the speed of a rotating spindle or vane immersed in the test liquid. The liquids commonly measured are lubricating oils and the like; heavier (non-Newtonian) liquids such as paints and paper coatings require more complex devices, e.g., Brookfield and Krebs-Stormer.

See also **Viscosity**.

VISCOSE PROCESS. The best-known process for making regenerated cellulose (rayon) by converting cellulose to the soluble xanthate, which can be spun into fibers and then reconverted to cellulose by treatment with acid. Wood pulp is steeped with 17–20% caustic soda; the resulting alkali cellulose is pressed to remove excess liquor and the soluble β- and γ-cellulose, and then shredded and aged. It is then treated with carbon disulfide and sodium hydroxide to form an orange, viscous solution of cellulose xanthate. After filtration and deaeration, this solution (viscose) is forced through minute spinnerette openings (or long slit dies in the case of cellophane) into a bath containing sulfuric acid and various salts such as sodium and zinc sulfate. The salts cause the viscose to gel immediately, forming a fiber or film of sufficient strength to permit it to be drawn through the bath under tension. At the same time the sulfuric acid decomposes the xanthate, converting the fibers to cellulose, in which form they are washed and dried.

See also **Xanthates**.

VISCOSITY. The internal resistance to flow exhibited by a fluid; the ratio of shearing stress to rate of shear. A liquid has a viscosity of one poise if a force of 1 dyne/square centimeter causes two parallel liquid surfaces one square centimeter in area and one centimeter apart to move past one another at a velocity of 1 cm/second. One poise equals 100 centipoises divided by the liquid density at the same temperature gives kinematic viscosity in centistokes (cs). One hundred centistokes equal on e stoke. To determine kinematic viscosity, the time is measured for an exact quantity of liquid to flow by gravity through a standard capillary. See also **Rheology**.

Water is the primary viscosity standard with an accepted viscosity at 20°C of 0.010019 poise. Hydrocarbon liquids such as hexane are less viscous. Molasses may have a viscosity of several hundred centistokes, while for a very heavy lubrication oil the viscosity may be 100 centistokes. There are many empirical methods for measuring viscosity.

See also **Saybolt Universal Viscosity**; and **Viscometer (or Viscosimeter)**.

VITAMIN. An organic compound that performs specific and necessary functions in humans, livestock, and other living organisms—even when it may be present in very small concentrations, at the milligram or microgram per 100 gram levels. The term *vitamine* was proposed by a Polish biochemist (Casimir Funk) in 1912 to designate substances required in trace amounts in the diet to prevent various nutritional-deficiency diseases. The principal vitamins are given in Table 1.

Nearly all vitamins are associated in some way with the normal growth function as well as with the maintenance and efficiency of living things. Various species are capable of synthesizing some of the vitamins from precursors that are present in the body. Synthesis is frequently by way of intestinal bacteria. In the case of vitamin D, substances in the skin combine with ultraviolet radiation from sunlight to yield the essential substance. Some vitamins, such as vitamin C, are specific, singular substances—in this case ascorbic acid. With other vitamins, there is a range of related compounds, as exemplified by the D, E, and K vitamins.

Because of inconsistencies in nomenclature, the B vitamins are not closely related as one might suspect. The B vitamins are different specific substances, and the use of the letter B to designate them indicates a degree of commonality that actually is not the case. Vitamin B_1 is thiamine, vitamin B_2 is riboflavin, vitamin B_6 is pyridoxine, vitamin B_{12} is cobalamin. Vitamins B_6 and B_{12}, for example differ markedly in function and structure. The alphabetical method of designation became complex and somewhat confusing as the various vitamins were recognized and studied over many years. During this period some substances were found to be identical with previously announced and described vitamins; or some substances were found not to be vitamins at all. Thus, over the years, the International Union of Pure and Applied Chemistry (I.U.P.A.C.) assigned new names to several of the vitamins.

The major vitamins are described in separate alphabetical entries in this book. Titles used for these entries have been selected on the basis of the most frequently used designations as of the early 1980s. In alphabetical order, the vitamins described in this book are: **Ascorbic Acid (Vitamin C)**; **Biotin**; **Choline and Cholinesterase**; **Folic Acid**; **Inositol**; **Niacin**; **Pantothenic Acid**; **Vitamin B_2 (Riboflavin)**; **Thiamine (Vitamin B_1)**; **Vitamin A**; **Vitamin B_6 (Pyridoxine)**; **Vitamin B_{12} (Cobalamin)**; **Vitamin D**; **Vitamin E**; and **Vitamin K**.

The daily requirements of vitamins by humans are summarized in the entry on **Diet**. The relationship between hormones and vitamins is described in the entry on **Hormones**. Vitamins also are mentioned frequently in descriptions of various fruits, vegetables, and other foodstuffs throughout the book. Vitamins also figure prominently in discussions of some of the diseases, scores of which are described in this book.

Loss of Vitamins in Processing

During the last several years, much research has gone into determining the loss in effectiveness of vitamins as various foods are processed. It is a common tendency on the part of consumers to regard any fresh food as representing perfection in terms of nutritive, including vitamin, value

TABLE 1. COMPARATIVE LOSSES OF VITAMINS FROM VEGETABLES (CANNING AND FREEZE PROCESSING)

		Loss of vitamins as compared with values of fresh cooke				
Method of preservation	Value	Vitamin A	Thiamine (B_1)	Riboflavin (B_2)	Niacin	Ascorbic acid (C)
Frozen, cooked (boiled), drained	mean	12%	20%	24%	24%	26%
	range	0–50%	0–61%	0–45%	0–56%	0–78%
Canned, drained solids	mean	10%	67%	42%	49%	51%
	range	0–32%	56–83%	14–50%	30–65%	28–67%

TABLE 2. COMPARATIVE LOSSES OF VITAMINS FROM FRUITS

		Loss of vitamins as compared with values of fresh products				
Method of preservation	Value	vitamin A	Thiamine (B_1)	Riboflavin (B_2)	Niacin	Ascorbic acid (C)
Frozen (not thawed)	mean	37%	29%	17%	16%	18%
	range	0–78%	0–66%	0–67%	0–33%	0–50%
Canned, solids and liquids	mean	39%	47%	57%	42%	56%
	range	0–68%	22–67%	33–83%	25–60%	11–86%

and, conversely, to regard processed foods as nutritionally inferior. Under normal circumstances, these observations are true. Because fresh foods frequently are stored for several days at temperatures well above their freezing points, there are vitamin losses in unprocessed produce. Ascorbic acid content in vegeTables, for example, can severely degrade during improper storage. The degradation of vitamin values depends a great deal upon the type of food substance, the particular vitamin, and the manner in which the raw food is processed. The consumer today also is protected by vitamin-fortified foods, where vitamins have been added to compensate for losses during processing, or, in some cases, to generally enrich the foods nutritionally. Losses of vitamins from fruits and vegeTables during processing are tabulated in Tables 1 and 2.

VITAMIN A. This substance also has been referred to as retinol, axerophthol, biosterol, vitamin A_1, anti-xerophthalmic vitamin, and anti-infective vitamin. The physiological forms of the vitamin include: Retinol (vitamin A_1) and esters; 3-dehydroretinol (vitamin A_2) and esters; 3-dehydroretinal (retinine-2); retinoic acid; neovitamin A; neo-b-vitamin A_1. The vitamin is required by numerous animal species. All vertebrates and some invertebrates convert plant dietary carotenoids in gut to vitamin A_1, which is absorbed. Most animal species store appreciable amounts of the vitamin in their livers, have low concentrations in the blood, and undetectable quantities in most other tissues. A deficiency of the vitamin produces a variety of symptoms, the most uniform being eye lesions, nerve degeneration, bone abnormalities, membrane keratinization, reproductive failure, and congenital abnormalities. Toxic symptoms from large doses of vitamin A are readily produced in animals and humans. Overdosage may cause irritability, nerve lesions, fatigue, insomnia, pain in bones and joints, exophthalmia, and mucous cell formation in keratinized membranes.

The principal physiological functions of this vitamin include growth, production of visual purple, maintenance of skin and epithelial cells, resistance to infection, gluconeogenesis, mucopolysaccharide synthesis, bone development, maintenance of myelin and membranes, maintenance of color and peripheral vision, maintenance of adrenal cortex and steroid hormone synthesis. Specific vitamin A deficiency diseases include xerophthalmia, nyctalopia, hemeralopia, keratomalacia, and hyperkeratosis.

In the rods of the retina, retinal is found combined with the protein *opsin*, the complex being called *rhodopsin* (visual purple). Although the entire series of reactions involved in dark vision has not been entirely worked out, the major steps in the cycle are quite clear. All-*trans*-retinol from the blood is oxidized by alcohol dehydrogenase (with NADP, nicotinamide adenine dinucleotide phosphate) to retinol which, in turn, is isomerized in the retina to 11-*cis*-retinal. This combines with opsin to form rhodopsin. On exposure to light, rhodopsin undergoes a sequence of changes with the eventual splitting off of retinal, which now has the all-*trans* configuration. This presumably can be reutilized in the retina by isomerization, or it can be reduced to retinol by alcohol dehydrogenase and returned to the circulation either as the free alcohol or as an ester.

The relatively recent observation, that retinoic acid can replace retinol or retinal for normal growth of animals, gave rise to further concepts in the biochemistry of vitamin A. Although retinoic acid cannot be demonstrated to be present normally in animal tissues, its formation by liver aldehyde dehydrogenase (NAD) and aldehyde oxidase has been accomplished, so that the molecule must be considered in the general scheme of vitamin A metabolism. When retinoic acid is given to animals as the only form of vitamin A, growth is normal, but the animals eventually become sterile and blind. This had led to the consideration that vitamin A may have at least three independent functions: (1) growth; (2) vision; and (3) reproduction.

The reversal of the oxidative pathway of vitamin A (retinol → retinal → retinoic acid) does not occur in the body. When retinoic acid is fed to animals, even in relatively large doses, there is no storage and, in fact, the molecule is rapidly metabolized and cannot be found several hours after administration. The metabolic products have not been fully identified. Several fractions from liver or intestine, isolated after administering retinoic acid marked with carbon-14, have been shown to have biological activity.

In 1912, Hopkins reported a factor in milk needed for the growth of rats. In 1913, Osborne and Mendel demonstrated that milk factor is fat soluble, and present in other fats also. McCollum and Davis, in 1913–1915, identified milk factor (fat-soluble A) in butter and egg yolk. In 1917, McCollum and Simmonds found xerophthalmia in rats due to lack of fat-soluble A. In 1920, Drummond renamed fat-soluble A, vitamin A. In 1930, Moore determined that carotene is a precursor of vitamin A. See also ???. During 1930–1937, Karrer et al. isolated and synthesized vitamin A. In 1935, Wald reported visual purple in retina to be a complex of protein and vitamin A.

Distribution and Sources. Provitamin carotenoids are contained in numerous foods, but of varying concentrations.

High vitamin A and procarotenoids content (10,000–76,000 I.U./100 grams).[1]. Carrot, dandelion green, kohlrabi, liver (beef, calf, chicken, pig, sheep), liver oil (cod, halibut, salmon, shark, sperm whale), mint, palm oil, parsley, spinach, turnip greens.

Medium vitamin A and procarotenoids content (1,000–10,000 I.U./100 grams). Apricot, beet greens, broccoli, butter, chard, cheese (except cottage), cherry (sour), chicory, chives, collards, cream, eel, egg yolk, endive, fennel, kale, kidney (beef, pig, sheep), leek greens, lettuce (butterhead and romaine), liver (pork), mango, margarine, melons (yellow), milk (dried), mustard, nectarine, peach, pumpkin, squash (acorn, butternut, hubbard), sweet potato, tomato, watercress, whitefish.

Low vitamin A and procarotenoids content (100–1,000 I.U./100 grams). Artichoke, asparagus, avocado, banana, bean (except kidney), berry

[1] One I.U. = 0.344 microgram vitamin A acetate = 0.3 microgram retinol.

(black-, blue-, boysen-, goose-, logan-, rasp-), Brussels sprouts, cabbage, carp, cashew, celery, cherry (sweet), clam, corn (maize), cowpea, cucumber, currant (red), grape, groundnut (peanut), hazelnut, herring, kumquat, leek, lentil (dry), lettuce, milk, okra, olive, orange, oyster, pea, pecan, pepper (sweet), pineapple, pistachio, plum, prune, rhubarb, rutabaga, salmon, sardine, squash (summer and zucchini), tangerine, walnut (black).

In higher plants, carotenoids are produced in green leaves. In animals, conversion of carotenoids to vitamin A occurs in the intestinal wall. Storage is in the liver; also kidney in rat and cat. Target tissues are retina, skin, bone, liver, adrenals, germinal epithelium. Commercial Vitamin A supplements are obtained chemically by extraction of fish liver; or synthetically from citral or β-ionone.

Bioavailability of Vitamin A. Factors which may cause a decrease in the availability of vitamin A include: (1) liver damage; (2) impaired intestinal conversion of carotenes; (3) impaired absorption (low bile); (4) loss in food preparation (cooking and frying—heat oxidation); (5) presence of antagonists; (6) illness, causing increased destruction and excretion of the vitamin. Increases in availability may result from: (1) storage in body (liver); (2) factors which stimulate intestinal conversion of carotenes—tetraiodothyronine (thyroxine), insulin; (3) absorption aids—bile, fat; and (4) dietary protein which mobilizes vitamin A from storage in liver.

Antagonists of vitamin A include sodium benzoate, bromobenzene, citral, oxidized derivatives of vitamin A, excessive concentrations of thyroxine, estrogens, vitamin E (as regards membrane permeability). Synergists include vitamins B_2, B_{12}, and E, ascorbic acid, thyroxine, testosterone, melanocyte-stimulating hormone (MSH), and somatotrophin growth hormone.

Unusual features of vitamin A as observed by some investigators include: (1) decreases serum cholesterol in large-quantity administration (chicks); (2) dietary protein required to mobilize liver reserves of vitamin A; (3) decreased quantities in tumors; (4) coenzyme Q_{10} accumulates in A-deficient rat liver; (5) Ubichromenol-50 accumulation in A-deficient rat liver; (6) retinoic acid functions as vitamin A except for visual and reproductive functions; (7) anti-infection properties and anti-allergic properties; (8) decreases basal metabolism; (9) detoxification of poisons in the liver aided by vitamin A; and (10) vitamin A is involved in triose → glucose conversions.

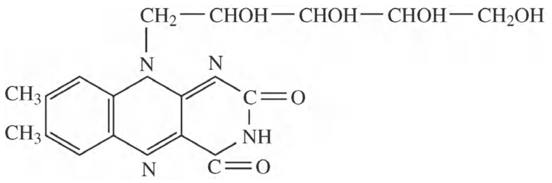
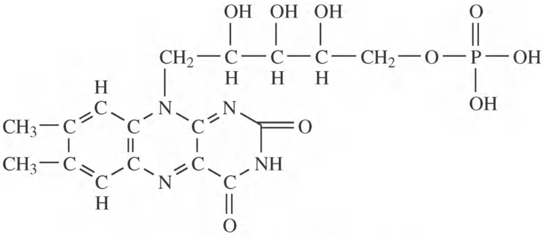
Facts About Vitamin A and Carotenoids:
http://www.cc.nih.gov/ccc/supplements/vita.html

VITAMIN B_2 (Riboflavin). Some earlier designations for this substance included vitamin G, lactoflavin, hepatoflavin, ovoflavin, verdoflavin. The chemical name is 6,7-dimethyl-9-d-l'ribityl isolloxazine. Riboflavin is a complex pigment with a green fluorescence. Riboflavin deficiency frequently accompanies pellagra and the typical lesions of both nicotinic acid and riboflavin deficiency are found in that disease. See also **Niacin**. Riboflavin, like nicotinic acid, forms an oxidation enzyme and, as such, acts as an oxygen carrier to the cell. The structure of riboflavin is:



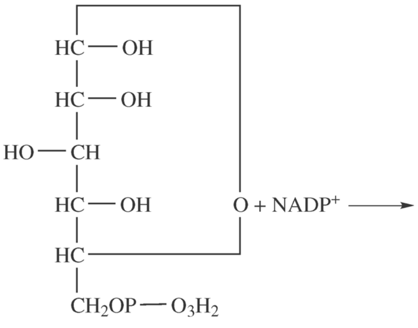
Disorders caused by a deficiency of riboflavin include anemia, cheilosis (a lip disorder); corneal vascularization, seborrheic dermatitis, and glossitis. Research leading to the current knowledge of riboflavin essentially commenced in 1917 when Emmet and McKim showed dietary growth factor for rats in rice polishings. In 1920, Emmet suggested the presence of several dietary growth factors in yeast concentrate, including the heat-stable component and B_1. The British Medical Research Council, in 1927, proposed that the designation B_2 be given to the heat-stable component. Warburg and Christian, in 1932, isolated yellow enzyme (containing riboflavin, FMN) from bottom yeast. In 1933, Kuhn isolated pure B_2 (riboflavin) from milk and recognized its growth-promoting activity. Several researchers (Kuhn et al.; Karrer et al.), in 1935, worked out the structure and synthesis of vitamin B_2, during which period it was named *riboflavin*. By 1954, Christie et al. had determined the structure and synthesized riboflavin dinucleotide (FAD).

Riboflavin has been shown to be a constituent of 2 coenzymes: (1) Flavin mononucleotide (FMN); and (2) flavin adenine dinucleotide (FAD). The structures are:



Flavin mononucleotide (FMN)

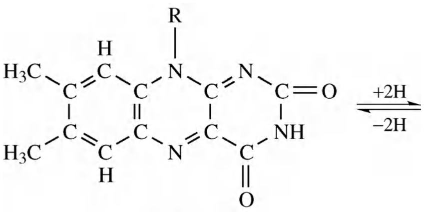
FMN was first identified as the coenzyme of an enzyme system that catalyzes the oxidation of the reduced nicotinamide coenzyme, NADPH (reduced NADP), to NADP (nicotinamide adenine dinucleotide phosphate). NADP is an essential coenzyme for glucose-6-phosphate dehydrogenase which catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconic acid. This reaction initiates the metabolism of glucose by a pathway other than the TCA cycle (citric acid cycle). The alternative route is known as the phosphogluconate oxidative pathway, or the hexose monophosphate shunt. The first step is:



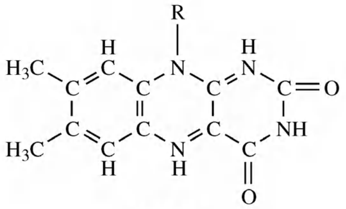
Glucose-6-phosphate

Most of the numerous other riboflavin-containing enzymes contain FAD. FAD is an integral part of the biological oxidation-reduction system where it mediates the transfer of hydrogen ions from NADH to the oxidized cytochrome system. FAD can also accept hydrogen ions directly from a metabolite and transfer them to either NAD, a metal ion, a heme derivative, or molecular oxygen. The various mechanisms of action of FAD are probably due to differences in protein apoenzymes to which it is bound.

The oxidized and reduced states of the flavin portion of FAD are:

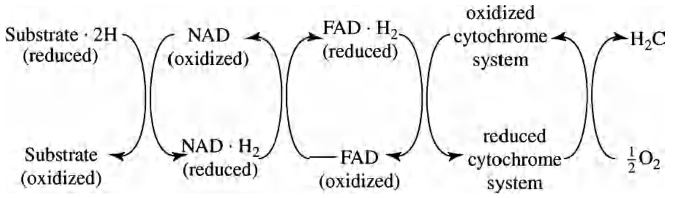


FAD
(oxidized)



FADH$_2$
(reduced)

In the biological oxidation-reduction system, reduced NAD (i.e., ADH) is reoxidized to NAD by the riboflavin-containing coenzyme FAD as shown by:



See also **Coenzymes**.

Distribution and Sources

Research indicates that all organisms require riboflavin. Endogenous sources exist in high plants, algae, some bacteria, and some fungi. All animals, some fungi and bacteria receive at least a partial supply of riboflavin from generation by intestinal bacteria. In the case of humans, there is a large dependence upon exogenous sources.

High riboflavin content (1000–10,000 micrograms/100 grams). Beef (kidneys, liver), calf (kidneys, liver), chicken (liver), pork (heart, kidneys, liver), sheep (kidneys, liver), yeast (killed)

Medium riboflavin content (100–1000 micrograms/100 grams). Almond (dry), asparagus, avocado, bacon, bean (kidney, lima, snap, wax), beef, beet greens, broccoli, Brussels sprouts, cashew, cauliflower, cheeses, chicken, chicory, corn (maize), cream, dandelion greens, eggs, endive, fish, goose, groundnut (peanut), kale, kohl-rabi, lamb, lentil (dry), milk, oats, parsley, parsnip, pea, pecan, pork, rice bran, soybean (dry), spinach, turkey, turnip greens, veal, walnut, wheat germ

Low riboflavin content (10–100 micrograms/100 grams). Apple, apricot, artichoke, banana, barley, beet, berry (black-, blue-, cran-, rasp-, straw-), cabbage, carrot, celery, cherry, coconut, cucumber, date (dry), eggplant, fig, grape, grapefruit, lettuce, melons, onion, orange, peach, pear, pepper (sweet), pineapple, plum, potato, radish, raisin (dry), rice, sweet potato, tangerine, tomato, turnip

Commercial riboflavin dietary supplements are prepared (1) by the fermentation process (bacteria or yeast); and (2) by chemical synthesis from alloxan, ribose, and *o*-xylene.

Precursors in the biosynthesis of riboflavin include purines, pyrimidines, and ribose. Intermediate in the synthesis is 6,7-dimethyl-8-ribityllumazine. In plants, riboflavin production sites are found in leaves, germinating seeds, and root nodules. Storage sites in animals are heart and liver, with small amounts in the kidneys. Riboflavin in overdose is essentially nontoxic to humans.

Bioavailability of Riboflavin

Factors which tend to decrease the availability of riboflavin include: (1) cooking, inasmuch as riboflavin is slightly soluble in water; (2) in some plant foods, availability is lower than might be expected because of bound forms; (3) decreased phosphorylation in intestines prevents absorption; (4) exposure of foods to sunlight; (5) enzymes required for breakdown are not present; (6) presence of gastrointestinal disease; and (7) diuresis. Riboflavin availability is increased by storage in heart, liver, and kidneys and by the presence of very actively producing intestinal bacteria.

Antagonists of riboflavin include isoriboflavin, lumiflavin, araboflavin, hydroxyethyl analogue, formyl methyl analogue, galactoflavin, and flavin-monosulfate. Synergists include vitamins A, B$_1$, B$_6$, and B$_{12}$, niacin, pantothenic acid, folic acid, biotin, tetraiodothyronine (thyroxine), insulin, and somatotrophin (growth hormone).

Determination of Riboflavin

Bioassay includes observance of the growth rate of rats; microbiological—*L. caseli*, and *L. mesenteroides*. Physicochemical methods include fluorimetry, paper electrophoresis, and polarography.

Unusual features of riboflavin as recorded by some researchers include: (1) High levels in liver inhibit tumor formation by azo compounds in animals; (2) free radicals are formed by light or dehydrogenation: flavine $\rightleftharpoons$ semiquinone: dihydroflavin+; (3) free vitamin is found only in retina, urine, milk, and semen; (4) substitution of adenine by other purines and pyrimidines destroys activity of flavin adenine dinucleotide (FAD); (5) phosphorylation of vitamin in intestines allows absorption as flavin mononucleotide (FMN); (6) blood levels decrease during life in humans: (7) brain content remains constant; (8) available in plants as FMN and FAD; (8) very concentrated in bull semen.

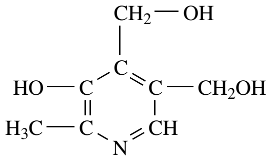
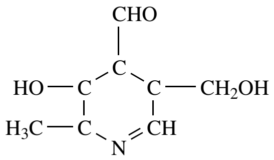
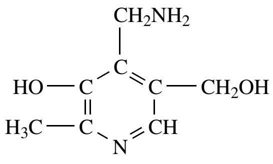
VITAMIN B$_6$ (Pyridoxine). Infrequently called adermine or pyridoxol, this vitamin participates in protein, carbohydrate, and lipid metabolism. The metabolically active form of B$_6$ is pyridoxal phosphate, the structures of which are:



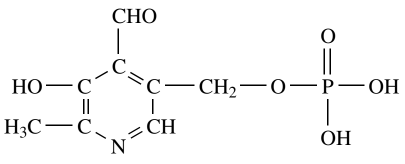
Pyridoxine



Pyridoxal



Pyridoxamine



Pyridoxal phosphate

Pyridoxal phosphate enzymes mediate the nonoxidative decarboxylation of amino acids. This mechanism is of primary importance in bacteria, but it may be essential to proper function of the nervous system in humans

by providing a pathway for the synthesis of a nerve impulse inhibitor, γ-amino-butyric acid from glutamic acid:

$$\underset{\text{Glutamic acid}}{HOOC{-}CH_2CH_2\underset{\underset{NH_2}{|}}{C}H{-}COOH} \xrightarrow{\text{Pyridoxal phosphate}} \underset{\gamma\text{-Aminobutyric acid}}{HOOC{-}\ CH_2CH_2CH_2NH_2} + CO_2$$

Pyridoxal phosphate is also a cofactor for transamination reactions. In these reactions, an amino group is transferred from an amino acid to an α-keto acid, thus forming a new amino acid and a new α-keto acid. Transamination reactions are important for the synthesis of amino acids from non-protein metabolites and for the degradation of amino acids for energy production. Since pyridoxal phosphate is intimately involved in amino acid metabolism, the dietary requirement for vitamin B_6 increases as the protein content of the diet increases.

The coenzyme especially participates in gluconeogenesis, production of neural hormones, bile acids, unsaturated fatty acids, and porphyrins.

A deficiency of the vitamin can result in lymphopenia, convulsions, dermatitis, irritability, and nervous disorders in humans. A deficiency in monkeys may cause arteriosclerosis, while in rats, acrodynia. Research indicates that all animals require vitamin B_6. Bacteria in intestines generate some of this vitamin, but relatively little is available to humans in this form. Endogenous sources are available to plants, fungi, and some bacteria.

In 1934, György cured a dermatitis in rats (not due to vitamins B_1 or B_2) with a yeast extract factor. In 1938, Lepkovsky isolated a similar factor from rice bran extract. In that same year, Keresztesy and Stevens isolated and crystallized pure B_6 from rice polishings. Also, in the same year, Kohn, Wendt, and Westphal synthesized pyridoxine and gave pyridoxine its present name. In the following year (1939), Stiller, Keresztesy, and Stevens established the structure of the vitamin. In 1945, Snell observed pyridoxal and pyridoxamine. The recognition of and establishment of B_6 requirements in humans was not achieved until 1953, by Snyderman et al.

In plants, the vitamin is present as pyridoxol-5-phosphate, pyridoxal-5-phosphate, or pyridoxamine-phosphate. In plants, production sites are found in fungi, cereal germ, and seeds.

Commercially, the vitamin is available as a dietary supplement in the compound pyridoxine hydrochloride. The compound can be synthesized by condensing ethoxy acetylacetone with cyanoacetamide (method of Harris and Folkers); or from oxazoles.

Distribution and Sources

Most fruits and vegetables are low in pyridoxine content, although most nuts are quite high. Cereals and a number of other substances have low-to-medium content.

High pyridoxine content (1,000–10,000 micrograms/100 grams). Groundnut (peanut), herring, liver (beef, calf, pork), molasses (black strap), rice (brown), salmon, walnut, wheat germ, yeast.

Medium pyridoxine content (100–1,000 micrograms/100 grams). Avocado, banana, barley, beef, Brussels sprouts, butter, cabbage, carrot, cauliflower, cod, corn (maize), eggs, flounder, grape, halibut, kale, lamb, mackerel, oats, pea, pear, pork, potato, rye, sardine, soybean, spinach, tomato, tuna, turnip, veal (brain, heart, kidney), whale, wheat, yam.

Low pyridoxine content (10–100 micrograms/100 grams). Apple, as paragus, bean, beet greens, cantaloupe, cheese, cherry, currant (red), grapefruit, lemon, lettuce, milk, onion, orange, peach, raisin, strawberry, watermelon.

Bioavailability of Pyridoxine

Factors which tend to decrease bioavailability of pyridoxine include: (1) Administration of isoniazid; (2) loss in cooking (estimated at 30–45%)—vitamin is water-soluble; (3) diuresis and gastrointestinal diseases; (4) irradiation. Availability can be increased by stimulating intestinal bacterial production (very small amount), and storage in liver. The target tissues of B_6 are nervous tissue, liver, lymph nodes, and muscle tissue. Storage is by muscle phosphorylase (skeletal muscle—small amount). It is estimated that 57% of the vitamin ingested per day is excreted. The vitamin exerts only limited toxicity for humans.

Precursors for biosynthesis of the vitamin include glycine, serine, or glycolaldehyde, although further research is required for further confirmation of these substances. Intermediates have not been identified. Antagonists of B_6 include 4-deoxypyridoxine, 4-methoxypyridoxine, toxopyrimidine, penicillamine, semicarbazide, and isoniazid. Synergists include ascorbic acid, biotin, epinephrine, folic acid, glucagon, niacin, norepinephrine, somatotrophin (growth hormone), and vitamins B_1, B_2, and E.

Determination of Vitamin B_6

As pointed out by investigators Gregory and Kirk (Department of Food Science and Human Nutrition, Michigan State University, East Lansing, Michigan), development of an adequate chemical procedure for the determination of biologically active forms of vitamin B_6 in foods has been a complex problem. Basic studies by Bonavita (1960), Toepfer et al. (1961), and Polansky et al. (1964) have demonstrated the feasibility of fluorometric measurement of pyridoxal (PAL), pyridoxamine (PAM), and pyrodixine (PIN) by conversion to PAL and reaction with potassium cyanide, forming the fluorphore 4-pyridoxic acid lactone. Various fluorometric methods have been applied to vitamin B_6 compounds in biological materials (Fujiita et al., 1955; Contractor and Shane, 1968; Loo and Badger, 1969; Takanashi et al., 1970; Fieldlerova and Davidek, 1974; Chin, 1975). The results of Chin suggested that interfering compounds may be present in the PAL fraction after column chromatographic separation of the B_6 analogs by the procedure of Toepfer and Lehmann (1961). In the Gregory-Kirk (1977) study, methods for improving chromatographic separation and fluorometric determination of vitamin B_6 compounds in foods were investigated. Their findings are presented in the reference indicated.

Traditionally, B_6 compounds also have been determined by bioassay, including rat and chicken growth assays.

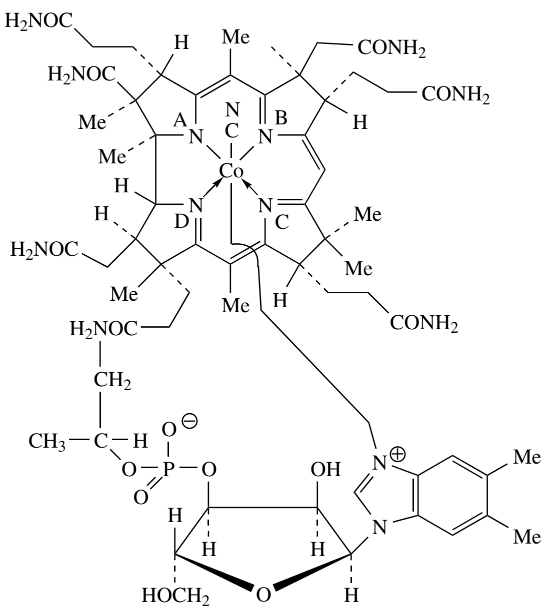
Facts About Vitamin B6:
http://www.cc.nih.gov/ccc/supplements/vitb6.html

VITAMIN B_{12} (Cobalamin). Sometimes also called cyanocobalamin, this vitamin is one of the more recent of the major B complex vitamins to be fully identified, with its structure not definitized (by Hodkin et al.) until 1955. The vitamin is required by most vertebrates, some protozoa, bacteria, and algae. Principal physiological functions include: (1) Coenzyme in nucleic acid, protein, and lipid synthesis; (2) maintains growth; (3) participates in methylations; (4) maintains epithelial cells and nervous system (myelin sheath); (5) erythropoiesis (with folic acid); (6) leukopoiesis. Deficiency diseases or disorders include retarded growth; pernicious anemia; megaloblastic anemia; macrocytic, hyperchromic anemia; glossitis; spinal cord degeneration; and sprue. The major physiological forms of B_{12} available include hydroxocobalamin (vitamin $B_{12a)}$ and aquocobalamin (vitamin $B_{12c)}$.

In 1926, Minot and Murphy controlled pernicious anemia using liver. In 1944, Castle demonstrated intrinsic factor needed to control pernicious anemia with liver. Rickes et al., in 1948, isolated and crystallized factor in liver controlling pernicious anemia. In that same year, Smith and Parker crystallized and designated liver factor as vitamin B_{12}. West demonstrated, in 1948, clinical activity of vitamin B_{12}, and, in 1955, Hodgkin et al. determined the structure of the vitamin. This is shown in Structure 1. Vitamin B_{12} is the only vitamin with a metal ion—in this case, cobalt.



Structure 1. Vitamin B_{12}

Surrounding the cobalt is a macrocyclic corrin ring that is comprised of four nitrogen-containing, five-membered rings joined through three methylene bridges. There is a similarity between this corrin ring and the dihydroporphyrin (chlorin) ring of chlorophyll.

Absorption of Vitamin B_{12}

This vitamin is not synthesized in animals, but rather it results from the bacterial or fungal fermentation in the rumen, after which it is absorbed and concentrated during metabolism. Among the known vitamins, this exclusive microbial synthesis is of great interest. One of the major results of vitamin B_{12} deficiency is pernicious anemia. This disease, however, usually does not result from a dietary deficiency of the vitamin, but rather by an absence of a glycoprotein ("gastric intrinsic factor") in the gastric juices that facilitates absorption of the vitamin in the intestine. Control of the diseases hence is either by injection of B_{12} or by oral administration of the intrinsic factor, with or without the vitamin injection.

There are two separate and distinct mechanisms for absorption of vitamin B_{12}. One mechanism is active, the other passive; both operate simultaneously. The active process is physiologically more important, since it is operative primarily in the presence of the small (1–2 micrograms) quantities of vitamin B_{12} made available for absorption from the average meal. This special mechanism, perhaps uniquely necessary for vitamin B_{12} because of its large size and polar properties, operates as follows. The normal gastric mucosa secretes a substance, called the *intrinsic factor of Castle*, which combines with free vitamin B_{12}. The complex travels down the intestine to the ileum, where, in the presence of calcium and pH above 6, it attaches to "receptors" lining the wall of the ileal mucosa. Vitamin B_{12} is then freed from intrinsic factor via a "releasing factor" mechanism of unknown nature, operating either at the surface of or within the ileal mucosal cell, and passes into the bloodstream. Thus, important requirements for normal absorption of vitamin B_{12} from food are: (1) the vitamin must be freed from its peptide bonds in food; (2) the gastric mucosa must secrete an adequate quantity of intrinsic factor; (3) the ileal mucosa must be sufficiently normal both structurally and functionally so that vitamin B_{12} may be absorbed across it.

Intrinsic factor is believed to be a glycoprotein or mucopolysaccharide with a molecular weight in the range of 50,000 and an end-group conformation like that of partly degraded blood group substance. The sole known role of intrinsic factor is to facilitate the transport of the large (molecular weight = 1,355) vitamin B_{12} molecule across the wall of the ileal mucosa and into the bloodstream. Antibodies to intrinsic factor exist in the serum of approximately half of all patients with pernicious anemia.

The second mechanism for vitamin B_{12} absorption is operative primarily in the presence of quantities of vitamin B_{12} greater than those made available for absorption from the average diet (i.e., quantities greater than about 30 micrograms). This mechanism is a passive one, probably diffusion, and most likely occurs along the entire length of the small intestine. It operates when patients with pernicious anemia (vitamin B_{12} deficiency due to inadequate or absent intrinsic factor secretion of unknown cause) are treated with large quantities (500 micrograms or more daily) of oral vitamin B_{12}. Such treatment is probably better than treatment with oral hog intrinsic factor, to which refractoriness often develops, but it is not as certain as treatment with monthly injections of vitamin B_{12}.

Deficiency Effects

Further elucidating on the physiologic functions and deficiency disorders of vitamin B_{12}, this vitamin is required for DNA (deoxyribonucleic acid) synthesis and, therefore, is necessary in every reproducing cell in humans for maintenance of the ability to divide. The vitamin functions coenzymatically in the methylation of homocysteine to methionine. It is important in several isomerization reactions, and as a reducing agent, and is probably of special importance in enzymatic reduction of ribosides to deoxyribosides. It is involved in protein synthesis, partly via its role in the conversion of homocysteine to methionine; in fat and carbohydrate metabolism, partly via its role in the isomerization of succinate to methylmalonate (which then may be decarboxylated to propionate), and in folate metabolism. Where these two vitamins interrelate, vitamin B_{12} appears to serve as a coenzyme and folate as a substrate; such is true in the vitamin B_{12}-mediated transfer of a methyl group from N^5-methyltetrahydrofolic acid to homocysteine, which is thereby converted to methionine.

Vitamin B_{12} is one of the most potent nutrients known; the minimal daily requirement for absorption by the normal adult is probably in the range of 0.1 microgram. This equals, for example, 1/500th of the minimal daily adult folate requirement, which is in the range of 50 micrograms.

As with all nutritional deficiencies, lack of vitamin B_{12} may arise from inadequate ingestion, absorption, or utilization, and from increased requirement or increased excretion. Deficiency of vitamin B_{12} produces megaloblastic (large germ cell) anemia, damage to the alimentary tract (glossitis being the most striking feature), and neurologic damage. The most classic neurologic sign of vitamin B_{12} deficiency is decreased ability to perceive the vibration of a tuning fork pressed against the ankles. This finding is associated with damage to the posterior and lateral columns of the spinal cord, and also with damage to the peripheral nerves. This damage occurs because vitamin B_{12} deficiency results in gradual deterioration of the myelin sheath, which is followed by deterioration of the axon. These processes occur slowly over months to years, and during this stage are reversible by treatment with vitamin B_{12}. However, when the nerve nucleus finally deteriorates, the neurologic damage becomes irreversible.

Distribution and Sources of Vitamin B_{12}. Vegetables, fruits, seeds, and nuts have a very low content of this vitamin.

High vitamin B_{12} content (50–500 micrograms/100 grams). Brain (beef), kidney (beef, lamb), liver (beef, calf, lamb, pork).

Medium Vitamin B_{12} content (5–50 micrograms/100 grams). Clam, crab, egg yolk, heart (beef, chicken, rabbit), kidney (rabbit), liver (chicken, rabbit), oysters, sardine, salmon.

Low Vitamin B_{12} content (0.5–5 micrograms/100 grams). Beef, cod, cheeses, chicken, eggs, flounder, haddock, halibut, lamb, lobster, milk, pork, scallops, shrimp, swordfish, tuna, whale.

Vitamin B_{12} dietary supplements are often prepared commercially by the fermentation of *S. griseus, S. aureofaciens, Propionibacterium*; or as a by-product of antibiotic production.

Certain species of bacteria and actinomycetes biosynthesize vitamin B_{12}. Precursors for this synthesis include glycine-corrin nucleus; δ-aminolevulinic acid-corrin nucleus; and methionine-corrin nucleus. Intermediates during the synthesis include porphobilinogen, α-D-ribosides of benzimidazole; 5,6-dimethylbenzimidazole; and α-ribazole. Antagonists of vitamin B_{12} include methylamide, ethylamide, anilide, lactone derivatives, pteridine, nicotinamide. Synergists include ascorbic acid, biotin, folic acid, pantothenic acid, thiamine, and vitamins A and E.

Bioavailability of Vitamin B_{12}

Factors which tend to decrease the availability of this vitamin include: (1) cooking losses, since the vitamin is heat labile; (2) cobalt deficiency in ruminants; (3) intestinal malabsorption or parasites; (4) lack of intrinsic factor; (5) intestinal disease; (6) aging; (7) vegetarian diet; (8) excretion

in feces; (9) gastrectomy. Factors which help to increase availability include: (1) administration of sorbitol; (2) synthesis by intestinal bacteria (not normally); (3) reduced temperature; and (4) presence of food in the stomach.

Although vitamin B_{12} is essentially considered nontoxic, polycythemia has been reported from excessive dosages. From 30 to 60% of the vitamin is stored in the liver; the remainder is found in the kidneys, lungs, and spleen. Target tissues are the central nervous system, kidneys, myocardium, muscle, skin, and bone.

Unusual features of vitamin B_{12} observed by some investigators include: (1) the cyanide group is an artifact of preparation; (2) the only vitamin synthesized in appreciable amounts only by microorganisms (possible in tumors); (3) only vitamin with a metal ion; (4) works with glutathione; (5) glutathione content decreased on B_{12} deficiency; (6) mitosis retarded in B_{12} deficiency; (7) requires intrinsic factor (enzyme) for oral activity; (8) increases tumor size (Rous sarcoma); (9) diamagnetic properties; (10) no acidic or basic groups revealed on titration (no pKa).

Additional Sources of B_{12}

Fermented soybean and fish products have been found to contain B_{12} (Lee et al., 1958). Nutritionally significant amounts of B_{12} also were found in the Indonesian fermented products, *ontjom* and *tempeh* (Liem et al., 1977). The microbial production of vitamin B_{12} in *kimchi*, Korean fermented vegetables, including cabbage, has been reported (Lee et al., 1958; Kim et al., 1960). The strain producing the vitamin during the fermentation was identified as *Bacillus megaterium*. As reported by Ro, Woodburn, and Sandine (1979), Foods and Nutrition Department and Department of Microbiology, Oregon State University, Corvallis, Oregon, inoculation of fermented foods with strains known to produce vitamin B_{12} has been evaluated as a vitamin enrichment method. Soybean paste inoculated with *Bacillus megaterium* and fermented was found to contain increased vitamin levels (Choe et al., 1963; Ke et al., 1963). Propionibacterium species widely used in the industrial production of vitamin B_{12} (Wuest and Perlman, 1968) have been recommended for vitamin fortification of some dairy products. Karlin (1961) fortified *kefir* with vitamin B_{12} by the addition of *Propionibacterium* to the kefir grains. Kruglova (1963) prepared vitamin-enriched curds from pasteurized cow's milk by fermentation with equal parts of cultures of lactic acid and propionic acid bacteria (2.5% each). The curds had approximately 10 times more vitamin B_{12} than when produced in the usual way with only lactobacilli. In 1979, Ro, Woodburn, and Sandine undertook to increase the vitamin B_{12} content in the production of kimchi. Changes in the ascorbic acid content during the kimchi fermentation were also observed.

Determination of Vitamin B_{12}

Microbial (using *L. leichmanii, O. malhamensis, E. gracilis*, etc.) bioassay methods are used, as are checking the effects of curative doses on experimental animals (chick, rat, etc.). Physicochemical methods used include spectrophotometry, polarography, and isotope dilution.

Facts About Vitamin B12:
http://www.cc.nih.gov/ccc/supplements/vitb12.html

VITAMIN D. Although the term "Vitamin D" is convenient to use in discussions of nutrition, this singular term is unsatisfactory when used in a strict biochemical context—because there are different substances, each of which is capable of performing vitamin D nutritional functions, namely, that of promoting growth, including bone growth, and preventing rickets in young animals. With reference to generalized terms used over the years in the development and refining of knowledge of related substances, such terms as *antirachitic vitamin, rachitamin, rachiasterol, cholecalciferol, activated 7-dehydrocholesterol*, etc., have been used. As pointed out later, some of these terms remain quite appropriate.

As a brief introductory summary, vitamin D substances perform the following fundamental physiological functions: (1) promote normal growth (via bone growth); (2) enhance calcium and phosphorus absorption from the intestine; (3) serve to prevent rickets; (4) increase tubular phosphorus reabsorption; (5) increase citrate blood levels; (6) maintain and activate alkaline phosphatase in bone; (7) maintain serum calcium and phosphorus levels. A deficiency of D substances may be manifested in the form of rickets, osteomalacia, and hypoparathyroidism. Vitamin D substances are required by vertebrates, who synthesize these substances in the skin when under ultraviolet radiation. Animals requiring exogenous sources include infant vertebrates and deficient adult vertebrates. Included there are vitamin D_2 (calciferol; ergocalciferol) and vitamin D_3 (activated 7-dehydrocholesterol; cholecalciferol).

The most important or at least the best-known members of the family of D vitamins are vitamin D_2 (calciferol), which is indicated in abbreviated form in Structure 1 and can be produced by ultraviolet irradiation of ergosterol, and vitamin D_3 [Structure 2], which may be produced by the irradiation of 7-dehydrocholesterol.

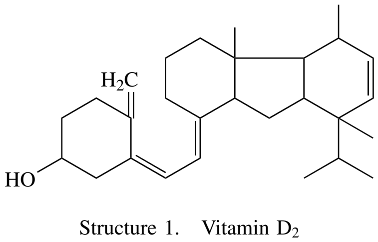
Nomenclature

Subscript numerals have a different connotation in connection with vitamin D substances than is true, for example, with B vitamins. Vitamins B_1, B_2, B_6, B_{12}, etc., represent individual substances which have little or no chemical resemblance to each other and perform different metabolic functions. The various vitamin D's, however, have very similar structures, differing only in the side chains, and perform the same functions.

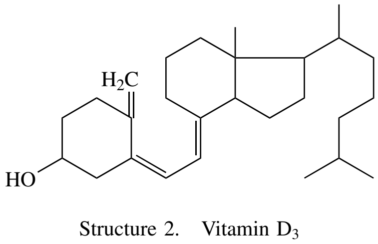
Biochemical Requirements

There are several unique features exhibited by the D vitamins. First, they are not required nutritionally at all if the organism has access to ultraviolet light (which is present in sunlight). Some animals, kept away from ultraviolet light, require so little D vitamins that the need cannot be demonstrated using ordinary diets. Rats, for example, exhibit a need for D vitamins when the calcium/phosphorus ratio in the diet is about 5:1 but not when it is the more usual 1:1. Chickens, on the other hand, exhibit a need even when the calcium/phosphorus ratio is "normal" (1.5:1).

Different species of animals respond distinctively to the different members of the vitamin D family. The most striking example of this is the fact that vitamin D_2 (calciferol) has practically no vitamin D activity for chickens. Rats respond about equally to D_2 and D_3. Human beings respond both to D_2 and D_3. Information as to how various animals react to



Structure 1. Vitamin D_2



Structure 2. Vitamin D_3

the other less known forms of vitamin D is largely lacking and for practical reasons is not sought after.

Members of the vitamin D family are extremely difficult to isolate and identify in pure form from any source. Fish liver oils are rich sources, and vitamins D_2 and D_3 have been isolated from them. Most ordinary foods are such poor sources in terms of amounts present, that the presence of D vitamins in them has not been demonstrated. Sterols that can be converted into some form of vitamin D by ultraviolet light are, however, widespread, and it may be inferred that D vitamins are often present even when their presence has never been demonstrated.

The requirements of animals for D vitamins in terms of actual weight are extremely small. It is estimated that human beings need about 400 international units of vitamin D per day. Since an international unit of vitamin D corresponds to 0.025 microgram of crystalline vitamin D, this means that the daily human requirement is about 0.01 milligram. Foods can contain as little as 0.02 parts per million of vitamin D and yet furnish an ample supply on the basis of the foregoing estimate.

Excessive dosages of D vitamins have caused excessive calcification and damage (hypervitaminosis). The full story of vitamin D dosage remains obscure. It has been observed, for example, that some "susceptible" children do not respond to the usual doses, but require 5,000–10,000 units per day to keep them free from rickets. There are other children that are afflicted with "vitamin D-resistant rickets" who do not respond even to these high doses, but may do so when doses of the order of 500,000–1,000,000 units are administered. Although unclear, it would seem that in some individuals the vitamin D has difficulty in getting through to where it is needed.

For many years it has been recognized that all cells need calcium to function because their growth and development is related to changes in their intracellular calcium content. Reasoning further, it has been postulated that calcium may serve as a cellular regulatory agent. Growing interest has been shown by investigators, in a steroid that is derived from vitamin D and that regulates the amount of calcium in the animal's blood. This substance has been referred to as a hormone. It is 1,25-dihydroxyvitamin D_3 and is metabolized from vitamin D. In response to a skeletal need for calcium, the hormone is secreted by the kidney and transported to the intestine and bones. Many authorities believe that parathyroid hormone is involved in signaling the kidney to release 1,25-$(OH)_2D_3$. Hypoparathyroid patients lack parathyroid hormone and fail to make 1,25-$(OH)_2D_3$. The result is an abnormally low concentration of calcium in the blood, producing severe bone disease. DeLuca and associates have used 1,25$(OH)_2D_3$ along with calcium to correct deficits in serum calcium concentrations of a limited number of patients. Corticosteroid therapy of long duration is known to produce bone disease. Corticosteroids are frequently administered to persons with rheumatoid arthritis, systemic lupus erythematosis, and asthma, in addition to persons who have received transplants. Some investigators have found that large doses of vitamin D tend to overcome the adverse effects of the corticosteroids. Findings to date essentially are the results of clinical applications rather than based upon a more detailed knowledge of the molecular mechanisms that operate in the metabolism of D vitamins.

Chronology of Vitamin D Substances

In 1918, Mellanby produced experimental rickets in dogs. In 1919, Huldschinsky ameliorated rachitic symptoms in children with ultraviolet radiation. Hess, in 1922, showed that liver oils contain the same antirachitic factor as sunlight. In that same year, McCollum increased calcium deposition in rachitic rats with cod liver oil factor. In 1924, Steenbook and Hess demonstrated irradiated foods have antirachitic properties. It was in 1925 that McCollum named antirachitic factor as vitamin D. In 1931, Angus isolated crystalline vitamin D (calciferol). In 1936, Windaus isolated vitamin D3 (activated 7-dehydrocholesterol).

Rickets

Vitamin D deficiency (also calcium deficiency) produces a condition known in children as *rickets* and in adults as *osteomalacia*. The bones and teeth of children with rickets are poorly formed and soft. A child with rickets frequently has malformed limbs, especially bowlegs. Blood clotting may be impaired, and, in extreme cases, there may be disturbances of the nervous system. An improvement in the level of calcium in the diet, along with vitamin D or parathyroid extract when required, brings about a hardening of the bones, but leaves them misshapen if deformity has already occurred. Adults, particularly pregnant or nursing women, also require vitamin D because calcium and phosphorus are continually dissolving from bones; and vitamin D is necessary for their utilization. Rickets is not to be confused with the entirely unrelated Rickeetsial group of diseases (Rocky Mountain fever, etc.) that are of virus origin.

Distribution and Sources

Fruits, nuts, and grains are not sources of vitamin D. Animal sources predominate.

High Vitamin D content ($1{,}000 - 25 \times 10^6$ *I.U./100 grams*).[1] Liver oils from: Bonito, cod, halibut, herring, lingcod, sablefish, sea bass, soupfin shark, swordfish, tuna.

Medium Vitamin D content (*100–1,000 I.U./100 grams*). Egg yolk, herring, kippers, lard, mackerel, margarine, pilchards, salmon, sardine, shrimp, tuna.

Low Vitamin D content (*10–100 I.U./100 grams*). Beef, butter, cheeses, cod roe, cream, eggs, grain oils, halibut, horse meat, liver (beef, calf, lamb, pork), milk (vitamin D fortified),[2] veal, vegetable oils.

Bioavailability

Factors which tend to cause a decrease in available vitamin D substances include: (1) liver damage; (2) presence of antagonists; (3) presence of phytin in gut; (4) low bile salts in gut; (5) high pH in gut; (6) destruction of intestinal flora; and (7) excretion in feces. Factors that enhance availability include: (1) storage in liver and skin; (2) absorption aids, such as bile salts; (3) decrease in pH of lower intestine; and (4) irradiation by ultraviolet. Antagonists of vitamin D include toxisterol, phytin, phlorizin, cortisone, cortisol, thyrocalcitonin, and parathormone. Synergists include niacin, parathormone (concentration dependent), and somatotrophin (growth hormone).

Dosages exceeding 4000 I.U./day may cause varying degrees of toxicity in humans. Symptoms include anorexia, nausea, thirst, and diarrhea. There also may be polyuria, muscular weakness, and joint pains. Serum calcium increases and calcification of soft tissues (arteries, muscle) may commence. Arterial lesions and kidney injury have been noted in rats.

In the biosynthesis of vitamin D substances, precursors include cholesterol (skin + ultraviolet radiation) in animals; ergosterol (algae, yeast + ultraviolet radiation). Intermediates in the biosynthesis include preergocalciferol, tachysterol, and 7-dehydrocholesterol. Provitamins in very small quantities are generated in the leaves, seeds, and shoots of plants. In animals, the production site is the skin. Target tissues in animals are bone, intestine, kidney, and liver. Storage sites in animals are liver and skin.

Commercial vitamin D dietary supplements are prepared by the irradiation of ergosterol, 7-dehydrocholesterol; or by extraction of fish liver oils.

Unusual features of vitamin D substances noted by some investigators include: (1) vitamin has hormonal qualities due to internal synthesis; (2) vitamin D2 has little activity for chickens—various species differ in response to the vitamin; (3) vitamin D substances may play a role in aging calcification phenomena, especially in skin; (4) the vitamin can mimic rickets with a high-calcium–low-phosphorus diet; (5) the vitamin can mimic osteomalacia under same conditions; (6) the vitamin is absorbed through skin; (7) the vitamin activates transport of heavy metals by intestinal cells; (8) the vitamin has an exceptionally long half-life (days to weeks); (9) furred and feathered animals obtain some vitamin D as the result of grooming and licking; (10) fishes are believed to obtain vitamin D from marine invertebrates; (11) the vitamin has been found useful in the treatment of lead poisoning.

Determination of Vitamin D

Bioassay techniques involve testing rats on antirachitic qualities. An important physicochemical method involves reaction with antimony trichloride.

See also entries on **Calcium**; **Hormones**; **Lipids**; and **Phosphorus**.

[1] One I.U. = 0.025 microgram vitamin D_3.

[2] Milk is normally a poor source of vitamin D. Since milk forms a major part of the diet in many countries, particularly for children, the product is commonly fortified with vitamin D substances.

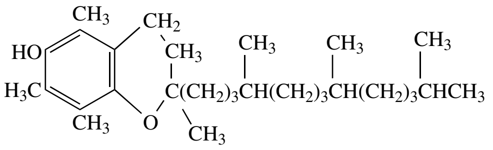
Facts About Vitamin D: http://www.cc.nih.gov/ccc/supplements/vitd.html

VITAMIN E. Sometimes referred to as the *antisterility vitamin*, factor X (an earlier designation), chemically vitamin E is alpha-tocopherol, the structure of which is:



Alpha-tocopherol

Active analogues and related compounds include: dl-α-Tocopherol; 1-α-tocopherol; esters (succinate, acetate, phosphate), and β, ζ_1, ζ_2-tocopherols. The principal physiological forms are D-a-tocopherol, tocopheronolactone, and their phosphate esters.

The physiological functions of vitamin E substances include: (1) bio logical antioxidant; (2) normal growth maintenance; (3) protects unsaturated fatty acids and membrane structures; (4) aids intestinal absorption of unsaturated fatty acids; (5) maintains normal muscle metabolism; (6) maintains integrity of vascular system and central nervous system; (7) detoxifying agent; and (8) maintains kidney tubules, lungs, genital structures, liver, and red blood cell membranes.

In livestock and laboratory animals, a deficiency of vitamin E substances may cause degeneration of reproductive tissues, muscular dystrophy, encephalomalacia, and liver necrosis. Considerable research is required to fully determine supplementation of livestock diets unless typical symptoms of a deficiency appear. Symptoms have appeared where there are selenium deficiencies in the soil and where there are excessive levels of nitrates in the soil. "White muscle" is the term used to describe a condition of muscular dystrophy in cattle.

In 1922, Evans and Bishop reported dietary factor "X" needed for normal rat reproduction. In that same year, Matill found dietary factor "X" in yeast and lettuce. Evans et al., in 1923, found factor "X" in alfalfa, butterfat, meat, oats, and wheat. The designation *factor "X"* was changed to *vitamin E* by Sure in 1924. In 1936, Evans et al. demonstrated that vitamin E belongs to the tocopherol family of compounds. During that year, these researchers isolated several active tocopherols and found a-tocopherol to be the most active of the number. Fernholz, in 1938, determined the structure of vitamin E. It was first synthesized by Karrer during that same year. During the interim between 1938 and 1956, several tocopherols were identified and studied. It was in 1956 that Green observed the eighth in the family of tocopherols.

The tocopherols were identified as naturally occurring oily substances and the first three were characterized as alpha, beta, and gamma forms, the biological activity of which decreased in that order.

Vitamin E substances are necessary for the normal growth of animals. Without vitamin E, the animals develop infertility, abnormalities of the central nervous system, and myopathies involving both skeletal and cardiac muscle. The antioxidant activity of the tocopherols is in reverse order to that of their vitamin activity. Muscular tissue taken from a deficient animal has an increased rate of oxygen utilization. The tocopherols are so widely distributed in natural foods that a spontaneous deficiency is infrequent unless diseases of the gastrointestinal or biliary system hinder absorption. Symptoms indicating a vitamin E deficiency include: (1) Red blood cell hemolysis, creatinuria, xanthomatosis and cirrhosis of gall bladder, steatorrhea (in young), cystic fibrosis of pancreases (in young), poorly developed muscles. Rats, dogs, monkeys, and chickens display muscular dystrophy; myocardial degeneration is observed in dogs and rabbits; resorption of fetus, degeneration of germ epithelium, disturbance of estrus cycle are observed in rats; hepatic necrosis is shown in rats; encephalomalacia and vascular degeneration is manifested in chickens.

Role of Vitamin E in Humans

The fundamental needs for vitamin E in humans have long been established. There are factors associated with this vitamin, however, that have created controversy and disagreement among highly qualified professional people. Although nearly every vitamin, at one time or other, has been used unwisely (in retrospect) in the treatment of human diseases, perhaps no other vitamin substance has aroused more discussion among clinicians than vitamin E. Because deficient animals develop a form of myopathy, it was natural to test the therapeutic efficacy of vitamin E in various forms of progressive muscular dystrophy and in diseases of the reproductive system. Enthusiastic claims have been made, and refuted, by investigators. From the standpoint of solid evidence, as of the early 1980s, the principal advantage of administering vitamin E lies exclusively in those instances where a vitamin E malabsorption syndrome exists. Associated with this fundamental situation are hemolytic anemia of premature infants; diseases caused by poor fat and oil absorption, and intermittent claudication (limping). A 1979 Institute of Food Technologists "Food Safety and Nutrition Panel" reported no incidence of vitamin E deficiency. Three underlying reasons were cited for this: (1) ample storage in adipose tissue; (2) slow elimination from the body; and (3) prevalence in foods. Significant amounts are present in vegetable oils and margarine (70% of the average daily intake), cereal products, fish, meat, eggs, dairy products, and leafy green vegetables.

Cure-all claims for the vitamin appear to stem from the vitamin's antioxidant properties and subsequent ability to neutralize harmful free radical products of oxidation. This had led to vitamin E administration for diseases of the circulatory, reproductive, and nervous systems, increased athletic and sexual endurance, and protection against aging and air pollution effects. Although some claims have been verified by animal studies, evidence is not conclusive for humans. Elderly individuals have resorted to vitamin E in hopes of slowing the aging process. The idea is not unfounded, for in the laboratory, the nutrient neutralizes radicals normally contributing to aging pigment formation. Neutralization within humans, however, remains unproven.

Distribution and Sources

Oily substances are, by far, the best natural sources of vitamin E.

High vitamin E content (50–300 milligrams/100 grams). Corn (maize) oil, cottonseed oil, margarine, safflower oil, soybean oil, wheat germ oil.

Medium vitamin E content (5–50 milligrams/100 grams). Alfalfa, apple seeds, asparagus, barley, cabbage, chocolate, coconut oil, groundnut (peanut), groundnut (peanut) oil, olive oil, rose hips, soybean (dry), spinach, wheat germ, yeast.

Low vitamin E content (0.5–5 milligrams/100 grams). Apple, bacon, bean (dry navy), beef, beef liver, blackberry, Brussels sprouts, butter, carrot, cauliflower, cheeses, coconut, corn (maize), corn (maize) meal, eggs, flour (whole wheat), kale, kohlrabi, lamb, lettuce, mustard, oats, oatmeal, olive, parsnip, pea, pear, pepper (sweet), pork, rice (brown), rye, sweet potato, turnip greens, veal, wheat.

Production sites for vitamin E biosynthesis occur in nuts, seeds, cereal germ, green leaves, legumes. Biosynthesis also occurs in some microorganisms. Precursors for biosynthesis include mevalonic acid and phenylalanine (probably these compounds with side chains). Considerably more research is required to pinpoint the exact precursors. Tocotrienol occurs as an intermediate in the biosynthesis.

Commercial production of vitamin E tocopherols is by way of molecular distillation from vegetable oils.

Antagonists of the tocopherols include α-tocopherol quinone, oxidants, cod liver oil, and thyroxine. Synergists include ascorbic acid, estradiol,

somatotrophin (growth hormone), testosterone, and vitamins A, B_6, B_{12}, and K.

Bioavailability of Vitamin E

Factors which tend to reduce availability of the vitamin include: (1) presence of antagonists; (2) mineral oil ingestion; (3) presence of vitamin E oxidation products; (4) occurrence with other less active analogues; (5) excessive excretion in feces; (6) impaired fat absorption; (7) chemical binding in foods; (8) cooking losses (vitamin is heat and oxygen labile); (9) losses in frozen storage, steatorrhea, and variability of natural sources. Factors which may increase absorption include: (1) Storage of vitamin in adipose and muscle tissues; (2) esterification, which increases stability; (3) use of unprocessed fresh food sources; and (4) absorption aids, such as bile salts.

Storage sites for the tocopherols in the body include muscle and adipose tissues and the liver. Target tissues include the adrenals, pituitary, kidney, genital organs, muscles, liver, lungs, and bone marrow.

Unusual features of vitamin E substances as observed by various investigators include: (1) the vitamin may be involved in aging mechanisms by protecting unsaturated fatty acids and membranes against free radicals; (2) only D-isomers occur naturally; (3) vitamin E is replaceable by selenium salts in therapy of rat and pig liver necrosis, and chick exudative diathesis; (4) vitamin E is replaceable by coenzyme Q (see also **Coenzymes**) and antioxidants for certain symptoms of vitamin E deficiency, but not for all, e.g., red blood cell hemolysis, resorption gestation not affected; (5) species differences in response to vitamin E treatment of similar symptoms, e.g., muscular dystrophy—positive in rabbits, negative in humans; (6) other tocopherols are only slightly active as compared with vitamin E; (7) vitamin content is decreased in tumors.

Alpha-Tocopherol and Nitrosamine Formation

Because of the growing concern, commencing in the late 1970s, as regards the formation of *N*-nitrosamines, such as dimethylnitrosamine and *N*-nitrosopyrrolidine, upon cooking of certain meat products cured with sodium nitrite, a number of investigators began studies to find materials that may inhibit nitrosamine formation. Reporting in late 1978, W.J. Mergens and a team of investigators (Hoffmann–LaRoche Inc., Nutley, New Jersey) observed that *N*-nitrosopyrrolidine has been found in fried bacon, but not in raw bacon (Fazio et al., 1973; Fiddler et al., 1974), apparently because of the influence of heat in accelerating the reaction of nitrite with the amine group of proline or its decarboxylated product, pyrrolidine, formed in frying (Archer et al., 1976; Hwang and Rosen, 1976). The effect of ascorbic acid in inhibiting nitrosamine formation has been demonstrated by various workers both *in vitro*and *in vivo* (Mirvish et al., 1972, 1973; Kamm et al., 1973, 1975; Greenblatt, 1973; Ivankovic et al., 1973).

The promising contribution of adding tocopherol to bacon, along with sodium ascorbate, to inhibit nitrosamine formation undertaken by Mergens and associates is reported in detail in the Mergens et al. reference (1978).

Determination of Vitamin E

Bioassay methods include measurements of quantity required to prevent fetal resorption; and for red blood cell hemolysis (in rat). Measurements also are made of liver storage in the chick. Physicochemical methods used include colorimetric two-dimensional paper chromatography.

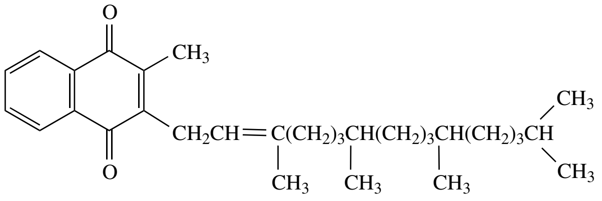
Facts About Vitamin E: http://www.cc.nih.gov/ccc/supplements/vite.html

VITAMIN K. Sometimes referred to as the *antihemmorhagic vitamin*, and, earlier in its development, the prothrombin factor or Koagulationsvitamin, vitamin K is a substituted derivative of naphthoquinone and occurs in several forms. The designation *phylloquinone*, or K_1, refers to 2-methyl-3-phytyl-1,4 naphthoquinone; the designations *farnoquinone* and *prenylmenaquinone*, or K_2, refer to 2-difarnesyl-3-methyl-1,4-naphthoquinone. *Menadione*, sometimes called oil-soluble vitamin K3, is 2-methyl-1,4-naphthoquinone. The structure of phylloquinone is:



Generally, when vitamin K substances are absent or deficient in the diet of animals, including humans, a hemorrhagic disorder will appear. Young fowls that are allowed to continue on a deficient diet for extended periods will ultimately die of internal hemorrhage, or from extensive bleeding from small external wounds. Fowls experience difficulty in absorbing vitamin K from the intestine, whereas humans, rats, and dogs absorb it readily and normally obtain their requirement form intestinal bacteria without need of dietary supplementation. If, however, bacterial synthesis is inhibited by the use of sulfa drugs or certain antibiotics, the disease will develop, unless the diet is supplemented with some form of vitamin K. When there is a decrease in the amount of bile salts in the intestine, as in obstructive jaundice, vitamin K is absorbed in such small amounts that the disease will also ensue. The use of vitamin K also is suggested to control and prevent the disease in premature babies. Vitamin K_1 is also able to reverse the hemorrhagic condition resulting from the administration of dicumarol to animals.

It has been reported that vitamin K_1 and several of the vitamin K_2 homologues are capable of restoring electron transport in solvent-extracted or irradiated bacterial and mitochondrial preparations. Other reports suggest that vitamin K is concerned with the phosphorylation reactions accompanying oxidative phosphorylation. The capacity of these compounds to exist in several forms, e.g., quinone, quinol, chromanol, etc., appears to strengthen the proposal that links them to oxidative phosphorylation. Information has suggested that vitamin K acts to induce prothrombin synthesis. Since prothrombin has been shown to be synthesized only by liver parenchymal cells in the dog, it would appear that the proposed role for vitamin K is not specific for only prothrombin synthesis, but applicable to other proteins.

In 1929, Dam reported chicks on a synthetic diet develop hemorrhagic conditions. In 1935, Dam named vitamin K as the missing factor in synthetic diets. In that same year, Almquist and Stokstad demonstrated

the presence of vitamin K in fish meal and alfalfa. In 1939, Dam and Karrer isolated vitamin K from alfalfa; and, in that same year, Doisy isolated K_1 from alfalfa, K_2 from fish meal, and demonstrated differences of the two substances. Also, in 1939, MacCorquodale, Cheney, and Fieser determined the structure of vitamin K_1. In that same year, Almquist and Klose synthesized vitamin K_1 for the first time. In 1941, Link et al. discovered dicoumarol, an anticoagulant and antagonist of vitamin K.

In addition to compounds previously mentioned, active analogues and related compounds include menadiol diphosphate, menadione bisulfite, phthicol, synkayvite, menadiol (vitamin K_4), and compounds designated as vitamins K_5, K_6, and K_7.

Many species require vitamin K. The vitamin is frequently administered to poultry via feedstuffs. Intestinal bacteria, normally functioning, supply the vitamin to the human body.

In the therapy of deep venous thrombosis, heparin is commonly administered. This drug takes effect immediately to prevent further thrombus formation. However, heparin is regarded as a hazardous drug and possibly may be the leading cause of drug-related deaths in hospitalized patients who are relatively well. Usually administered intravenously, preferably by pump-driven infusion at a constant rate rather than by intermittent injections, it sometimes may cause major bleeding, which is particularly hazardous if it is intracranial. The action of heparin can be terminated almost immediately by intravenous injection of protamine sulfate, but where there may be less urgency, vitamin K_1 may be used. The vitamin preparation may be administered intravenously, intramuscularly, or subcutaneously.

Vitamin K is also an antagonist of warfarin, which is sometimes used in rodenticides. Pets that have been exposed to warfarin-containing poisons may be saved from death by internal hemorrhaging through the immediate administration of vitamin K.

Vitamin K is sometimes used in the treatment of viral hepatitis.

It has been found that vitamin K analogues possess an ability to insert themselves into the oxygen-binding cleft of hemoglobin. This may result in hemolysis (dissolution of red blood corpuscles with liberation of their hemoglobin).

See also **Anticoagulants**.

Distribution and Sources

Some fruits, vegetables, and nuts, as well as meat products, contain good sources of K vitamins. Intestinal bacteria, M. phlei, synthesize it.

High vitamin K content (*100–300 micrograms/100 grams*). Beef kidney, beef liver, cabbage, cauliflower, pork, soybean, spinach.

Medium vitamin K content (*10–100 micrograms/100 grams*). Alfalfa, egg yolk, pine needles, potato, strawberry, tomato, wheat (bran, germ, whole).

Low vitamin K content (*0–10 micrograms/100 grams*). Carrot, corn (maize), milk, mushroom, parsley, pea.

Commercial production of vitamin K is by column chromatography of fish meal extracts. In biosynthesis, precursors include polyacetic acid (ring); acetate (side chain). Intermediates include dehydroquinic acid (ring); farnesol (side chain).

Bioavailability of Vitamin K

Factors which decrease availability of the vitamin include: (1) biliary obstruction; (2) liver damage—cirrhosis, toxins; (3) poor food preparation (vitamin is strong-acid, alkali, light, and reduction labile); (4) impaired lipid absorption in gut; (5) presence of antagonists; (6) ingestion of mineral oil; (7) sterilization of gut with antibiotics and sulfa drugs; and (8) excessive excretion in feces. Availability may be increased by way of storage in the liver and absorption aids, such as bile salts.

Antagonists of vitamin K substances include dicoumarol, sulfonamides, antibiotics, α-tocopherol quinone, dihydroxystearic acid glycide, salicylates, iodinin, warfarin. Synergists include ascorbic acid, somatotrophin (growth hormone), and vitamins A and E.

General symptoms of a vitamin K deficiency include hypoprothrombinemia, increased bleeding and hemorrhage, increased clotting time, and neonatal hemorrhage. Internal hemorrhage is a symptom in chicks. Usually the vitamin is nontoxic, but, in humans, very excessive dosages can cause thrombosis, vomiting, and porphyrinuria. Target tissues are liver and vascular system. Small quantities are stored in liver.

Determination of Vitamin K

A vitamin K deficient chick assay may be made; or physicochemical techniques, including polarographic methods, spectrophotometry of pure solutions, and prothrombin time determinations, may be used.

VITAMIN K (Blood Coagulation). See **Anticoagulants**.

VITREOUS STATE. When certain liquids are cooled fairly rapidly, crystals do not form at a definite temperature, but the viscosity of the liquid increases steadily until a glassy substance is obtained. A glass may be thought of as a disordered amorphous solid, or as a supercooled liquid, which only devitrifies into the crystalline state after extremely long standing. Glasses are optically isotropic, which explains their value in optical instruments. The property of forming a glass is possessed particularly by the oxides of silicon, boron, germanium, arsenic, phosphorus, etc., and by many organic compounds, especially those containing several hydroxyl groups per molecule. See Fig. 1.

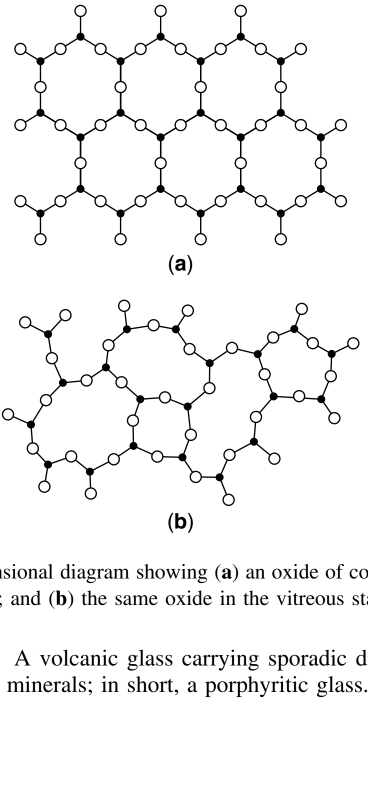

Fig. 1. Two-dimensional diagram showing (**a**) an oxide of composition X_2O_3 in the crystalline form; and (**b**) the same oxide in the vitreous state

VITROPHYRE. A volcanic glass carrying sporadic distinct crystals of feldspar and other minerals; in short, a porphyritic glass.

VIVIANITE. The mineral vivianite is a hydrous iron phosphate, $Fe_3(PO_4)_2 \cdot 8H_2O$, its monoclinic crystals are usually prismatic or blade-like but may be in massive forms. Vivianite has one perfect cleavage; hardness 1.5–2; specific gravity 2.58–2.68; luster, pearly on cleavage; faces, otherwise vitreous; colorless, when freshly exposed, but becoming blue or brownish with the alteration of the ferrous to ferric iron; transparent to translucent. Vivianite is an associate of pyrrhotite, pyrite and copper and tin ores. It is found also in clay beds forming the so-called blue iron earth which is common and of wide distribution in peat bogs. Vivianite is found in Rumania; Bavaria; Cornwall in England; and elsewhere in Europe; Australia; Bolivia; and Greenland. In the United States it occurs in New Jersey, Delaware, and Colorado. This mineral was named by Werner after the English mineralogist J.G. Vivian, its discoverer.

VOIDS. Empty spaces of molecular dimensions occurring between closely packed solid particles, as in powder metallurgy. Their presence permits barriers made by powder metallurgy techniques to act as diffusion membranes for separation of uranium isotopes in the gaseous diffusion process.

See also **Diffusion**.

VOLATILE. Having a low boiling or subliming temperature at ordinary pressure; in other words, having a high vapor pressure, as ether, camphor, naphthalene, iodine, chloroform, benzene; or methyl chloride.

VOLATILE OILS. The volatile oils are distinguished from the fixed oils by the fact that a drop of one of the former does not leave a spot on paper. Members of certain plant families, such as the *Labiatae*, contain a larger percentage of such oils than do other families. But volatile oils are in no sense restricted to any small group, nor are they found only in certain tissues. Sometimes, certain parts may be principally used for the oils, as the seeds of the *Umbelliferae*.

Various methods are used in extracting the oils from the plant tissue. Many are distilled with water or steam, the oil being carried over with the distillate. In others, as for example oil of bitter almonds, the oil develops in the tissues only after fermentation. It is then obtained by distillation. Another method, and one especially used for more delicate and valuable oils, is called "enfleurage." In this method the flowers containing the oil are spread as a thin layer over a layer of lard or olive oil. The latter absorbs the delicate oil in the flowers, after which distillation may separate the volatile oil from the other.

VOLATILE OILS (Flavoring). See **Flavonoids**.

VOLATILE ORGANIC COMPOUNDS. Any hydrocarbon, except methane and ethane, with vapor pressure to or greater than 0.1 mm Hg.

VOLATILITY PRODUCT. The product of the concentrations of two or more ions or molecules that react to produce a volatile substance. The volatility product is analogous to the solubility product, except that, when it is exceeded, the substance escapes from the system by volatilization rather than precipitation. As with the solubility product, if any of the reacting ions or molecules have a numerical coefficient greater than one, then the concentration term of that ion or molecule is raised to the corresponding power.

VOLTAIC CELL. Two conductive metals of different potentials, in contact with an electrolyte, which generate an electric current. The original voltaic cell was composed of silver and zinc, with brine-moistened paper as electrolyte. Semisolid pastes are now used; electrodes may be lead, nickel, zinc, of cadmium.

See also **Solar Cell (Photovoltaic Cell)**.

VOLUME (Standard). The volume occupied by one gram molecular weight of a gas at 0°C and a pressure of 1 standard atmosphere.

VON BAEYER, ADOLF (1835–1917). A German chemist who received the Nobel prize for chemistry in 1905. He was recognized for his services in the advancement of organic chemistry and the chemical industry, through his work on organic dyes and hydroaromatic compounds. He was educated in Berlin under the direction of Bunsen and Kekule. He was a professor in Strasbourg and Munich. Many discoveries included barbituric acid and the molecular structure of indigo.

VULCANIZATION. A physiochemical change resulting from cross-linking the unsaturated hydrocarbon chain of polyisoprene (rubber) with sulfur, usually with application of heat. The precise mechanism that produces the network structure of the cross-linked molecules is not completely known. Sulfur is also used with unsaturated types of synthetic rubbers; some types require use of peroxides, metallic oxides, chlorinated quinones, or nitrobenzenes. Natural rubber can be vulcanized with selenium, organic peroxides, and quinone derivatives, but these have limited industrial use; high-energy radiation curing is and important innovation.

See also **Rubber (Natural)**.

W

WACKER REACTION. The oxidation of ethylene to acetaldehyde in the presence of palladium chloride and cupric chloride.

WAD. The mineral wad, sometimes called *bog manganese*, occurs in amorphous masses, and consists of mixtures of manganese oxides, MnO_2 and MnO, and oxides of other metals such as copper, lead, cobalt, and iron. It is bluish- to brownish-black, usually soft enough to soil the fingers and often porous and light. It is not a distinct mineral species.

WAFER (Silicon). See **Semiconductors**.

WAGNER-JAUREGG REACTION. Addition of maleic anhydride to diarylethylenes with formation of bis adducts that can be converted to aromatic ring systems.

WAGNER-MEERWIN REARRANGEMENT. Carbon-to-carbon migration of alkyl, aryl, or hydride ions. The original example is the acid-catalyzed rearrangement of camphene hydrochloride to isobornyl chloride.

WAKSMAN, SELMAN A (1888–1973). American microbiologist (Nobel prize winner in 1952) and professor at Rutgers University. He was the first to use the term *antibiotic* to designate the mold produced antibacterial substances discovered by Fleming in 1928. He became the outstanding authority in this field.

WALDEN INVERSION. Inversion of configuration of a chiral center in bimolecular nucleophilic substitution reactions. See also **Rearrangement (Organic Chemistry)**.

WALLACH, OTTO (1847–1931). German chemist who received the Nobel prize for chemistry in 1910 for recognition of his services to organic chemistry and the chemical industry by his pioneer work in the field of alicyclic compounds. His mentors were Hofmann and Wahler, and he worked at the University of Bonn under Kekule. He studied pharmacy and did work on terpenes, camphors, and essential oils. This was followed by research in aromatic oils, perfumes, and spices. His research of terpenes revealed their significance in sex hormones and vitamins. Ethereal oils and industrial uses were made possible by his work.

WARFARN. See **Anticoagulants**.

WASTE (Nuclear) Management. See **Nuclear Reactor**.

WASTES AND POLLUTION. The approach to reducing waste and abating pollution is complex and sometimes even controversial among the experts. Differences arise because not all of the facts are on hand. The basic chemistry and physics of the Earth's three waste "sinks"—the atmosphere, the hydrosphere, and the lithosphere—remain poorly understood. Although there is consensus among both technologists and the lay public that serious environmental pollution problems exist and indeed are worsening, there are differences pertaining to details and priorities. Environmental scientists and engineers are influenced by factors that are not exclusively scientific, but that are of a societal and economic nature as well. The populace in general is slow to accept changes in life-style preferences and habits, and commerce and business interests frequently resist the concept that environmental costs must be added to the other costs of doing business. Such conflicting factors minimize the key ingredient of attaining success—*dedication*.

Even in view of the aforementioned difficulties, impressive pollution abatement successes have been made, but unfortunately the pace of these programs has not kept up with the rate of the worsening environment. To illustrate the partial successes to date, one need only to compare the environmental status in the advanced industrial nations with the environmental damage found in the former Soviet Bloc, where environmental problems essentially were ignored.

Pathways to Environmental Correction

From an idealistic viewpoint, one may place the efforts for restoring the purity of the natural environment as falling along three pathways. This is an approximation, and the pathways are not mutually exclusive. Table 1 essentially is included as a checklist of the numerous actions that are being taken.

Pathway 1 includes those actions that are directed more toward eliminating or drastically reducing waste production—that is, efforts made to correct the cause (waste) rather than the effect (pollution). Had actions along these lines been taken years ago, the massive pollution experienced today most likely would not have occurred.

Pathway 2 actions recognize that, with current technology and societal attitudes coupled with economic factors, a considerable amount of pollution must be accepted. Actions along this pathway, however, can reduce the amount of wastes produced and hence resulting pollution.

Pathway 3 actions recognize the current inevitability of mass pollution, but which are directed toward reducing the long-term effects of waste disposal. In the past, pollution has occurred in somewhat of a step-like fashion (i.e., creation of the wastes in the first place, sometimes followed by unscrupulous means taken to "hide" or simply "forget" abandoned wastes, followed by waste site clean up). These problems occur simply because wastes have been or are being disposed of improperly.

Establishment of Regulations

When it became apparent that environmental protection could not be accomplished strictly on a voluntary basis, several of the advanced industrial countries were forced to take regulatory actions (circa mid-1960s). The problem was too complex and not sufficiently understood at the outset to institute complete legislation at one time. Consequently in the United States, for example, numerous special acts were passed but stretched out for several years. See Table 2 on p. 3701. This has resulted in difficult compliance and enforcement procedures.

Numerous scholars of the environment have noted several major differences between the way some of the advanced European industrial nations and Japan approach the problems of waste reduction and pollution abatement, and the general approach adopted by the United States over the years. The European countries referred to here notably are the Netherlands, Sweden, and Germany and, of course, do not include the former Soviet Bloc countries.

In the United States, *regulation* is by far the predominant controlling tool. The U.S. system is highly legalized. In the European countries and Japan, regulation is but one tool used.

Government regulators in the United States infrequently provide specific professional assistance to a firm with pollution problems. In the European countries mentioned and in Japan, regulatory personnel frequently work closely and cooperatively with industrial personnel in seeking solutions. In fact, in some cases, government grants are made available for remedial implementation.

The principal incentive for regulators in the United States is that of *developing* and *enforcing* regulations. Less emphasis is directed toward finding better methods for achieving improved results. In connection with the Superfund program, regulators are credited when pollution sites are cleaned up, but emphasis is given to *initiating* the action, with less accountability required where the cleanup has been found inadequate.

TABLE 1. WASTE-POLLUTION OPTIONS AND STRATEGIES (ABRIDGED)

PATHWAY 1

ELIMINATE OR GROSSLY REDUCE WASTES

Increase Life Span of Products

Reduce "junking" frequency. Design for corrosion and wear resistance; easy maintainability. Discourage frequent styling changes simply in interest of increasing marketing appeal.

Design Energy Efficiency into Products and Processes

Traditional processes for converting energy resources (fuels) into electricity, for example, are major polluters. Thus, end products and end processes should consume minimum energy to overcome "hidden" pollution costs. Considerable progress has been made to design more efficient heating and cooling systems (at manufacturing and consuming levels). New electric motor designs consume less energy. Electric lamp efficiency is increasing.

Use Less Pollutive Energy Sources

Check fuel BTU content vs. pollution generated. Also, pretreat fuels and design equipment to increase combustion efficiency.

Evaluate Nontraditional Energy Sources and Conversion Processes

Select least pollutive of common fossil fuels. Consider the feasibility of geothermal, hydro, solar, biomass, and other substitute energy resources. Nuclear power scores high as a non-polluter, with the exception of the radioactivity wastes. A new generation of nuclear reactors is underway that will increase safe operation manyfold. Much research on nontraditional energy resources continues, but generally technical problems have slowed the pace of progress. These efforts are addressed elsewhere in this encyclopedia. Check index.

Search for New Products and Processes (Substitutes)

Many existing products either generate excessive pollutants during their manufacture, require large amounts of energy (hence hidden polluters), or are adversely pollutive in their own right. Some agricultural chemicals and refrigerants exemplify the latter property. The techniques of organic synthesis provide an avenue to substitute product and process development. The recent development of new refrigerants to replace chlorofluorocarbons (ozone problem) and biological insecticides are examples. Some progress has been made in developing less-pollutive fuels for internal combustion engines and the substitution of new technology for traditional motive power, such as electric- and solar-powered vehicles.

De-emphasize Throw-Away Products

Although somewhat justifiable for certain hospital and medical products, these are very hazardous in wastes. This practice should be reevaluated. Other throw-away items, such as pens and cameras are designed because of marketing motivations and contribute to the waste-disposal load.

Eliminate Product Frills and Frivolous Products

Packaging engineers in recent years have contributed tremendously to waste creation. A substantial portion of household and restaurant wastes, for example, consist of packaging and shipping materials. The marketplace is full of junk merchandise.

Safely Transport Products

Moving polluting products from the manufacturing source to a consuming destination poses an environmentally damaging threat. Product containers must be designed to withstand forceful damage. In connection with petrochemical products, containers range in size from oil drums and chemical-containing carboys to ocean-going oil tankers.

J.S. Hirschhorn (Congressional Office of Technology Assessment) as early as 1988 presented a scholarly summary of waste reduction as the ultimate key to pollution abatement, "Waste reduction is the only way to save industry some of the escalating costs of the current waste-management system." The direct costs of waste disposal have increased some 50 times just over the past few years. Hirschhorn listed six steps to waste reduction:

1. Transfer the economic motivation for waste reduction to those engaged in the manufacturing process.
2. Motivate employees by crediting their performance records by meeting waste-reduction timetables established by management and for proposing waste-reduction concepts.
3. Seek technical assistance from outside sources to gain new viewpoints and incentives.
4. Conduct and maintain a waste-reduction audit.
5. Make waste reduction a lasting part of corporate culture. Approach waste-reduction goals today as energy conservation was stressed a decade or so ago.
6. Initiate a corporate-wide waste-reduction educational program.

PATHWAY 2

RECYCLE WASTE MATERIALS

Design Containers for Recycling

Although not always desirable from a marketer's or consumer's viewpoint, throw-away containers of all kinds contribute massively to the waste-handling problem and to pollution.

Design Products and Components for Recycling

Whereas the aluminum beverage container cannot be reused as such, the aluminum in the can may be reprocessed. The recycling of aluminum is one of the current successes along these lines. The production of raw aluminum from ores consumes enormous amounts of electricity and thus contributes to pollution. Similarly, for years scrap and junk yards have specialized in recycling other metals and all manner of machine parts. From the viewpoint of pollution, this is an excellent practice. Nonmetallics have proved to be more difficult to recycle (most plastics, for example), but much technical progress in this area is underway. Recycled wood fibers in paper products has enjoyed much success. Product designers are in an excellent position to consider the recycling potential of materials after the useful life of the product itself has expired.

Design Processes for Recycling

Cooling water is a prime utility in manufacturing and most notably in the chemical and petrochemical industries. Excellent progress has been made in recycling water instead of continuously dipping into natural water reservoirs. Use is made of cooling ponds and relatively simple water treating at the plant site, thus bypassing pollutive procedures. This also avoids thermal pollution of water source.

Much more complex substances than water should be considered for recycling. These would include the reuse of solvents, cleaning compounds, and, in some instances, using traditional waste components as sources of raw materials. Recovery of valuable materials from wastes may prove less expensive than procuring the same substance from a supplier.

Consider Wastes as Energy Resources

Some industries that produce large amounts of combustible solid wastes have used such materials to augment solid fuels, such as coal, to generate utility steam and hot water. See article on **Wastes as Energy Sources**.

Louis J. Thibodeaux (Louisiana State University and Director, EPA-Sponsored Hazardous Waste Research Center), in 1990, outlined the four *natural laws* of hazardous waste:

1. In converting thermal energy to useful work, a certain amount of waste (thermal) energy must be discharged into the environment.
2. It is impossible to recycle waste completely. Recycling is one aspect of waste minimization, not a solution.
3. Some fraction of the energy and material needed to drive processes and make products will always be degraded to waste that will have to be disposed of in an environmentally acceptable manner, such as incineration or some version of the solidification/fixation process.
4. Small waste leaks are unavoidable and acceptable. Ecosystems can handle small infusions of hazardous substance. Such discharges must, however, be made small so that there will be no harmful effects either locally or globally.

PATHWAY 3

Note: The actual disposition of waste into one of the Earth's "waste sinks" is the least attractive of pollution handling procedures. To date, however, dumping of waste remains the most widely used practice. Progress along Pathways 1 and 2 contribute to a progressive reduction in the tonnage of waste to be disposed and in the long term will alleviate the pollution problem in a major way.

In the advanced countries of the world, waste disposal is no longer a simple matter of venting gases and vapors into the atmosphere, or of finding the nearest creek or river, or of creating a landfill.

The carefree disposal of waste that took place several years ago resulted in a public outcry and the creation of numerous, often quite complex regulations. Thus, the polluting source today must take a number of costly actions prior to the ultimate disposal of the waste.

WASTE DISPOSAL—RELOCATING THE WASTE

Classify and Characterize the Waste

Regulations vary considerably, depending upon the nature of the waste. Hazardous (toxic) wastes are treated as a separate category by federal, state, provincial, and municipal regulatory agencies.

TABLE 1. (*continued*)

Pretreat Wastes Prior to Disposal
In addition to rigid requirements for hazardous wastes, other regulations may require various forms of pretreatment, such as sorting wastes into various categories in the interest of handling efficiency at waste sites, incinerators, and so on. Although they require handling as wastes, biodegradable wastes pose a lesser threat to long-term pollution and often require less stringent regulation.
Select an Appropriate Depository
Gases, vapors, and airborne particulates, unless present in minor amounts, generally will require postproduction treatment before venting to the atmosphere. Post-treatment is also frequently required for the disposal of liquid and solids. The topic of disposal site selection for liquids and solids is complex because there are so many classes of materials, including such diverse wastes as sewage, public building and household wastes, medical and hospital wastes, packaging wastes, transportation vehicle wastes, office wastes, and agricultural wastes. The lists numbers into the hundreds of categories.
In the case of fluids and solids, the Earth's hydrosphere or lithosphere are the only sinks available. For solids, some geological formations are much more appropriate than others. Some areas may appear suitable, but are found to exist over an aquifer (essentially an underground stream), and hence pollution can occur in the lithosphere and then pass along to the hydrosphere.
In the past, a number of polluters have used temporary waste storage means, such as aboveground tanks. Storage of radioactive wastes at nuclear power facilities is another example. In-plant storage or nearby polluter-owned sites must meet all current pollution regulations. These practices have been costly in retrospect. They have comprised many of the targets of the so-called Superfund.
Consider a Professional Waste-Handling Firm
Expert assistance (applying mainly to liquid and solid wastes) is available, but extreme caution must be taken in selecting such assistance. There have been several instances of fraudulent practices that have led to disastrous pollution and resulted in strict legal judgments against the initiating polluter.
Run Continuous Checks on Waste Disposal Costs
Where costs continue to spiral, this may provide the incentive to initiate actions along Pathways 1 and 2, which can lower pollution costs in the long term.
Consider the Inevitable Conflicts
Severe regulations are reasonably clear in terms of what a polluter can and cannot do. But tradeoffs do remain. A basic triangle of conflicting forces—that is, Energy vs. Economy vs. Environment—is described in article on Electric Power Production and Distribution.

In Japan and the European countries mentioned, regulators are rewarded for eliminating waste streams and cleaning up pollution. Regulators contribute technical expertise. In some cases, research is conducted in government laboratories in an effort to solve a particular pollution problem. The emphasis is on cooperation, rather than adjudication.

In the United States, regulations are highly detailed, sometimes overburdened with detail. They are drawn up so that they can withstand litigation and with little practical latitude in enforcement. Industry has no greater access to the regulators than does any other interest. This, unfortunately, tends to create a climate of confrontation rather than one of cooperation.

TABLE 2. WASTES AND POLLUTANTS REGULATORY STATUTES

(United States—partial list)

Clean Air Act
Clean Water Act
Comprehensive Environmental Response, Compensation, and Liability Act (popularly known as the Superfund)
Federal Insecticide, Fungicide, and Rodenticide Act
Food, Drug, and Cosmetic Act
Hazardous Materials Transportation Act
National Environmental Policy Act
Occupational Safety and Health Act
Resource Conservation and Recovery Act
Safe Drinking Water Act
Superfund Amendments and Reauthorization Act
Toxic Substances Control Act

Note: Most of these statutes have been enacted since the early 1970s.

In the European countries mentioned and in Japan, polluting firms are not required to pay for past practices that did not break former law, with the exception of sites that the polluter continues to own. In the United States, industrial polluters are liable for cleanup costs for sites to which they have contributed waste, even though no laws were broken when the pollution was created.

A more thorough examination of these policy differences is given in the Beecher/Rappaport reference listed.

Particular Attention Given to Hazardous Wastes. In addition to toxicity, hazardous wastes include materials that may become chemically reactive, including ignitability and explosibility, or that may be corrosive. Some toxic materials require extensive pretreatment prior to dumping. See Table 3 on p. 3701.

With the growing use of throwaway products in the hospital and medical field, there is an increasing danger stemming from *infectious wastes*. The ultimate disposal of millions of needles and condoms becomes a part of municipal wastes. The virulence of microorganisms under such conditions is poorly understood. Throwaway diapers not only contribute immensely

TABLE 3. REGULATOR'S CHARACTERIZATION OF HAZARDOUS WASTES

Toxicity
Definition of Extract: The liquid component of a solid waste and deionized water at a pH 5.0 that has been in continuous contact with the solid phase of the waste for a minimum of 24 hours.
Permissible Upper Limit of Contaminant:

	Milligrams/Liter
Arsenic	5.0
Barium	100.0
Cadmium	1.0
Chromium	5.0
Lead	5.0
Mercury	0.2
Selenium	1.0
Silver	5.0
Endrin insecticide	0.02
Lindane insecticide	0.4
Methoxychlor insecticide	10.0
Toxaphene insecticide	0.5
2,4-D (2,4-Dichlorophenoxyacetic acid)	10.0
Silvex 2-(2,4–5 Trichlorophenoxy propionic acid)	1.0

Reactivity
Any substance that:

- Is normally unstable and readily undergoes violent changes with detonations.
- eacts violently with water.
- Reacts with water to generate toxic gases, vapors, or fumes in a quantity that is dangerous to human health or the environment.
- Is capable of detonating or undergoing an explosive reaction when subjected to a strong initiating source or if heated when confined.
- Is capable of detonation or explosive decomposition or reaction at standard temperatures and pressures.
- Is normally considered explosive and that meets transportation regulations.
- Forms potentially explosive mixtures with water.
- Is a cyanide or a sulfide-bearing material that, when exposed to a pH between 2 and 12.5, can generate toxic gases, vapors, or fumes that are dangerous to human health or the environment.

Ignitability
Any substance that

- Is a liquid with a flash point of less than 60°C (140°F).
- Is a solid and is capable of causing fire through friction, absorption of moisture, or spontaneous chemical changes that, when ignited, burns so vigorously as to create a hazard.
- Is a compressed gas or oxidizer that does not meet transportation regulations.

Corrosiveness
Any aqueous liquid with a pH less than or equal to 2.0 or greater than or equal to 12.5.
Any liquid that corrodes steel at a rate greater than 0.006 meter (1/4-inch) per year.

to the volume of wastes to be handled, but also contain hosts of living microorganisms, the survival rate of which, under disposal conditions, have not been documented. The common childhood intestinal pathogens, such as retoviruses, hepatitis A virus, and the protozoans *Giardia* and *Cryptospordium*, have not been ruled out.

Incineration of Hazardous Wastes

One authority has commented that the greatest public health danger with medical waste in the United States is *substandard* incineration practices at local hospitals. It has been estimated that in the early 1990s there were about 6000 substandard medical-waste incinerators throughout the United States. The congressional Office of Technology Assessment (OTA) has estimated that air emissions of dioxin and heavy metals from these incinerators average from 10 to 100 times more per gram of waste burned than emissions from well-controlled municipal waste incinerators. Also, hospital incinerators produce toxic remains in the ashes that can contaminate surface and groundwater when dumped in landfills.

The problem is exacerbated in large and crowded communities. For example, there are well over 50 hospital incinerators in New York City. Most local hospital incinerators are not equipped with acid-gas scrubbers, which convert harmful airborne substances into harmless calcium salts. Nor are most incinerators equipped with electrostatic precipitators to capture particles that have adsorbed toxic flue gases.

Authorities report that quite the contrary conditions exist in several parts of Europe, notably Switzerland and Germany. Legislation in the early 1980s in Germany mandated the closing of hospital incinerators, requiring that medical wastes be sent to regional facilities, at which the latest in technology is deployed. Incinerator operators are given special training and require certification of their skills. Particular precautions are used in feeding such incinerators to protect plant workers. The incinerated remains are disposed of in specially lined landfills.

Recently, the technology of autoclaving instead of incineration has been proposed. Disinfection is achieved through the use of high-pressure steam, which assists in breaking the refuse down and ready for compacting.

German authorities also mandate strict regulations over the transport of medical waste, disallowing the transport of foodstuffs in trucks that also are used to handle medical wastes. Hospitals also are required to "tag" all refuse, designating such categories as "office, cafeteria, and general," "infectious" (including pathological body parts, syringes, needles), "radioactive," and "dangerous to handle" (such as scalpels, which must be placed in unopenable containers).

Considerable design effort has been invested in the improvement of incineration systems. D.A. Tillman (Ebasco Environmental) and associates report that "Rotary kilns have become the incinerators of choice for eliminating hazardous wastes in accordance with the U.S. Resource Conservation and Recovery Act, Superfund, and related legislation."

The Ebasco team points out, "A rotary kiln is basically a rotating cylinder that, typically, is refractory lined. The cylinder is tilted slightly (i.e., 3°) and the feed material goes into the upper end. A heat source is applied to the material, usually by combusting liquid or gaseous fuel within the kiln. Gravity moves the material through the cylinder, and it is discharged from the lower end. When rotary kilns are used for hazardous waste incineration, the gaseous products from the kiln are ducted to a secondary combustion chamber for subsequent destruction." Several overall system design configurations are possible. Generalized configurations are illustrated in Figs. 1 and 2. See Tillman reference listed.

J.F. Mullen (Dorr-Oliver Inc.) reports that fluidized bed incinerators have been used for municipal sludge and industrial waste incineration since the early 1960s for a variety of wastes (petroleum tank bottoms, sludge from pharmaceutical, pulp and paper, and nylon manufacturing operations), waste plastics, waste oils, and solvents. Fluid beds were first considered for incinerating hazardous wastes in the 1980s.

Advantages claimed for fluid bed technology include efficient combustion, ease of control for handling a variety of feeds, and reasonably low capital and operating costs. Specific advantages claimed for incinerating hazardous wastes include fuel savings and lower emissions of nitrogen oxides (NO_x) and metals. The principles of a fluid bed incinerator are illustrated in Fig. 3. Among the primary organic hazardous constituents (POHCs) of waste, the fluid-bed has successfully demonstrated its effectiveness in achieving 99.99% efficiency in removal of aniline, carbon tetrachloride, chloroform, chlorobenzene, cresol, para-dichlorobenzene, methyl methacrylate, naphthalene, perchloroethylene, phenol, tetrachloroethane, 1,1,1-trichloroethane, trichloroethylene, and toluene.

Soil-Washing Technology

Tons of earth per hour can be sifted and scrubbed clean of hazardous materials by using what may be called a heavy-duty industrial *washing machine*. Soils contaminated with hazardous or radioactive materials may

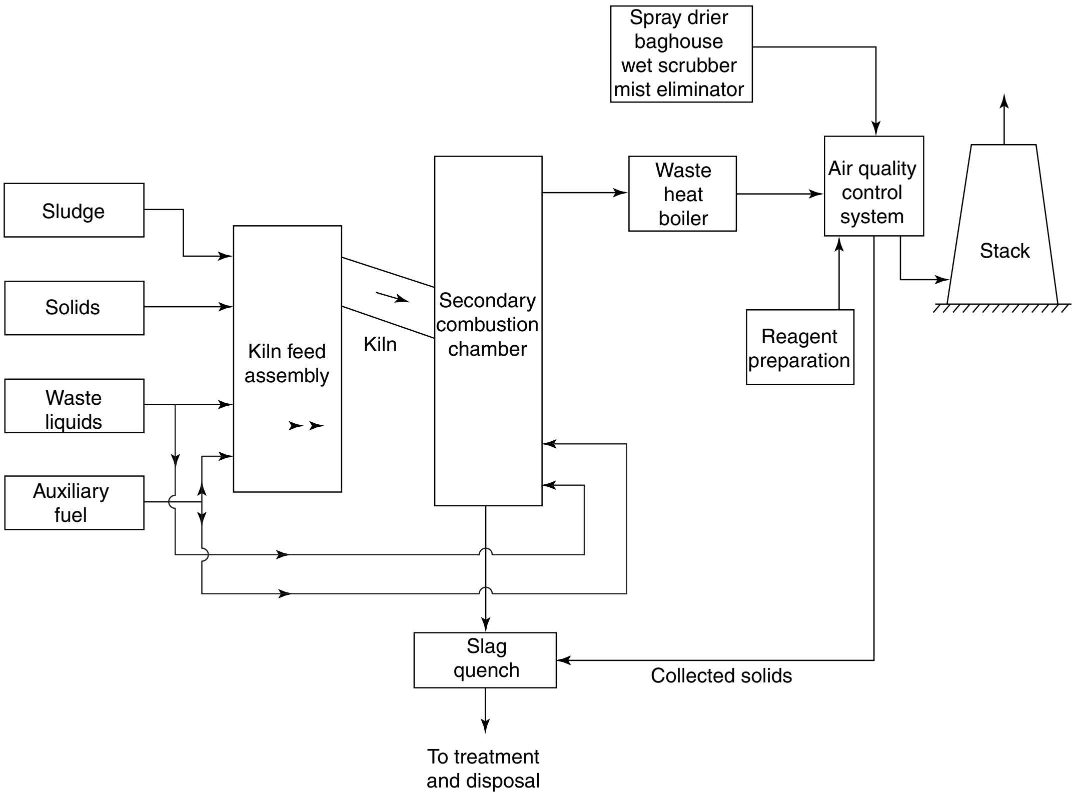

Fig. 1. Simplified flowsheet of incineration train in a hazardous waste treatment complex. (*After Tillman*)

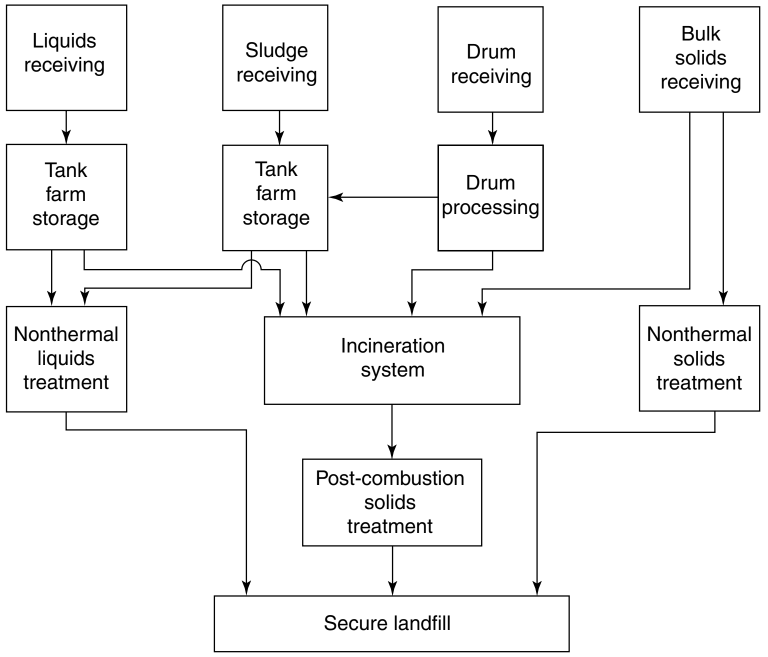

Fig. 2. Generalized flowsheet of a hazardous waste treatment system complex that utilizes a rotary kiln incineration system. (*After Tillman*)

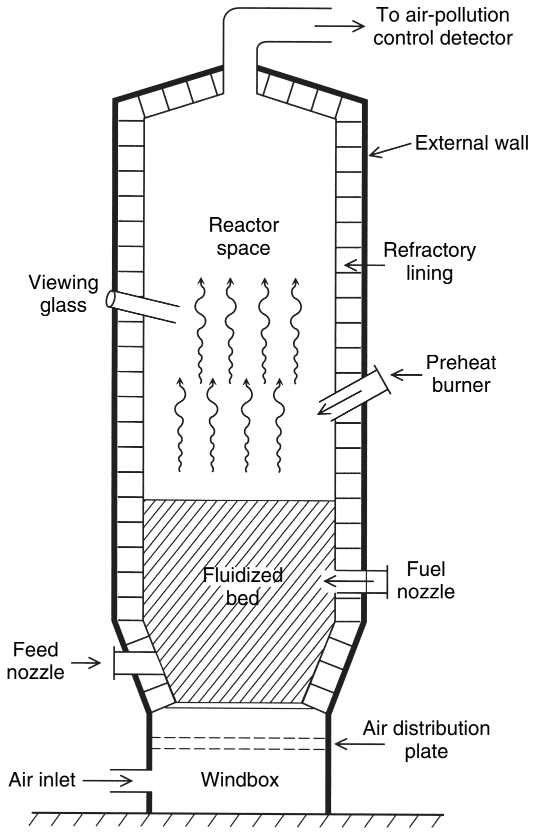

Fig. 3. Schematic diagram of a fluid-bed incinerator. Waste is injected into a bed of inert material that is fluidized by large quantities of air flowing upward through the unit. (*After Mullen*)

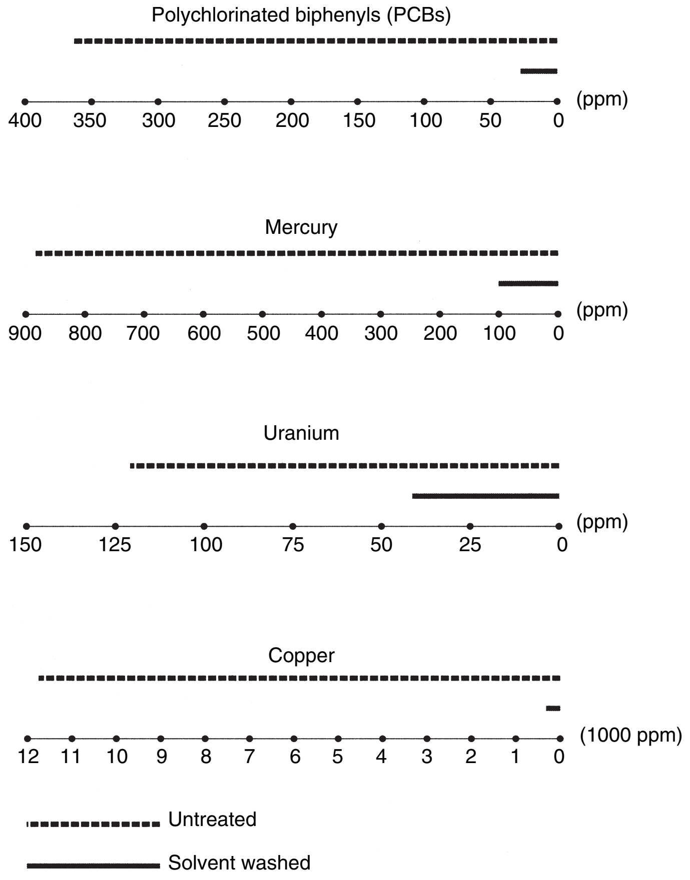

Fig. 4. Examples of performance of soil-washing process. (*Westinghouse Electric Corporation*)

be removed by washing. Contaminating material that "comes out in the wash" so to speak, such as copper, then can be recycled and reused by industry. Although not widely publicized, soil washing is not a new technology. It has been estimated that nearly 100,000 tons of contaminated soils are remedied in this manner each year in Europe. The bulk of these soils are sands contaminated with hydrocarbons and/or heavy metals. Westinghouse has developed a commercial unit.

The soil-washing process itself is environmentally benign. It is a closed-loop system, and thus no contaminants are discharged into the air or land. It is a permanent solution to many hazardous problems because it physically removes contaminants from the soil. Examples of tests made on the process are graphed in Fig. 4. Soil washers are mounted on truck trailers for mobility. A flow sheet of the process is given in Fig. 5.

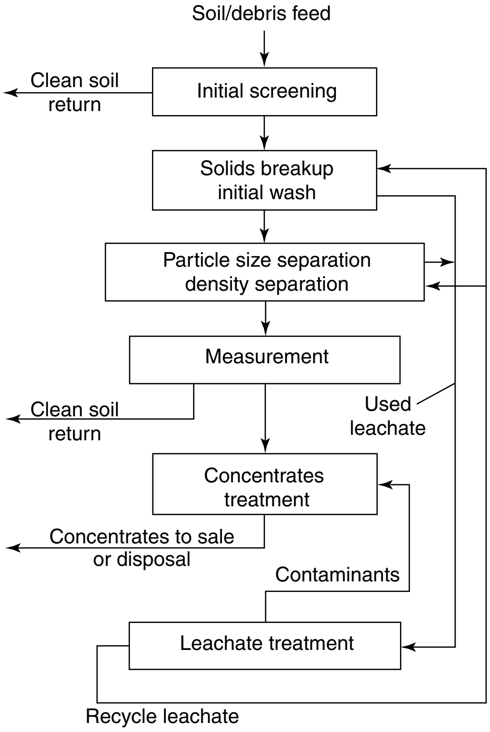

Fig. 5. Soil-washing process flowsheet. (*Westinghouse Electric Corporation*)

Fig. 6. Portable soil-washing machine shown here at a highway maintenance site used for removal of lead particles from the residue created when bridges and other metal structures are sand-blasted to remove old paint containing lead. There are numerous applications for such portable plants. (*Westinghouse Electric Corporation*)

In a particular application, Westinghouse unveiled in late 1992 equipment for removing lead particles from the residue created when bridges and other metal structures are sand-blasted to remove old lead-containing paint. This problem is commonly encountered by highway construction and maintenance personnel, but the system is not limited to such applications. It has been estimated that the method has achieved a two-thirds reduction in disposal costs as compared with burial or smelting without pretreatment. One of the first large-scale tests of the equipment was conducted by the Minnesota Department of Transportation. A portable soil-washing machine for highway work is shown in Figs. 6 and 7.

Soil washing is based on the use of water-based leachates, which are recycled continuously in the machine. The end products are a relatively clean, coarser soil fraction and a wash water containing finer soil particles and most contaminants. The small levels of organic contamination remaining in the coarser materials are removed readily with heat. The wash water, depending upon the specific contaminants, responds to various traditional treatment methods, such as bioremediation, air stripping, chemical precipitation, or membrane separation.

Recycling Plastic Wastes

Although plastic wastes in refuse are highly visible to the public, and thus have caused considerable consumer pressures on plastics manufacturers to take anti-pollution measures, disposal of plastics creates special problems in municipal incinerators because of the formation of some toxic gases. In terms of dumpsite disposal, the absence of biodegradability results in long-term solids buildup. Actually, on a weight basis, however, plastics only comprise 7% of municipal wastes, as shown in Table 4.

The principal plastics that show up in municipal wastes are the polyethylenes, polystyrenes, and polypropylenes. These include polyethylene terephthalate (PET) used in soft drink containers, high-density polyethylene (HDPE), used in milk jugs, and polystyrene, used in fast-food containers, which, incidentally, were first banned in Oregon (1989).

As early as 1989, 7 billion plastic soft drink containers were produced in the United States and nearly an equivalent tonnage in Europe. As of

TABLE 4. MAJOR MATERIALS IN MUNICIPAL WASTES

Material	Percent by weight
Paper products	40
Yard waste	18
Food waste (garbage)	12
Glass	8
Plastics	7
Steel/metals	7
Other	8
	100
Principal Classes of Plastics	
Low-density polyethylene (LDPE)	24
High-density polyethylene (HDPE)	19
Polystyrene	14.5
Polypropylene	14.5
Polypropylene terephthalate (PET)	4.5
Other plastics	23.5
	100.0

early 1991, it was reported that about 28% of the PET bottles produced in the United States were recycled, yielding over 20 million pounds of PET for subsequent use in making carpet yarn, fiberfill for clothing, nonfood containers, automobile parts, fencing, and industrial strapping. A doubling of these amounts was expected by 1995.

A principal plastic reclaiming process used was developed in the Netherlands by a resin manufacturing firm. In this process, after removal of labels and base cups by machine, the bottles (clear or green) are color sorted and granulated. The PET flake is then washed to remove glue. Closure material is separated by flotation from the PET. The remaining PET is dried and sifted for fines and then is ready for reuse.

In 1989, seven of the leading plastics producers in the United States formed the National Polystyrene Recycling Company, with a 1995 target for achieving a minimum of a 25% recycling rate for polystyrene. A pilot recycling center was set up in Leominster, Massachusetts.

A joint venture of a leading plastics manufacturer and a major waste management firm was established in 1990 to recycle PET and HDPE materials. The plan was that two existing plants would be joined by three additional recycling operations by 1994. Jointly, the plants would recycle about 200 million pounds of these plastics per year. Taken in perspective, however, this is a small quantity of the total of 1.5 billion pounds (PET) and 6.5 billion pounds (HDPE) disposed each year in the United States.

Still another leading plastics manufacturer commenced operation recently for recycling 400 million pounds/year of plastic film and rigid containers. Following a pilot-plant test run, a wide variety of polyethylene materials can be processed. These include polyethylene wrap, lawn and grocery bags, and containers (detergent, bleach, and motor oil), as well as plastic milk and juice bottles and PET soft drink and liquor containers. When in full operation, the plant will serve a 500-mile (∼800-km) radius area. It is projected that new applications for the recycled materials will displace some of the requirements for virgin plastic and nonplastic materials. Food applications of recycled material are not in the current plans because of the special problems involved in altering the color and other physical properties of the recycled resins.

Plastic materials recycling poses a serious problem when plastic refuse is received in a commingled state. Because of the great variety of plastic products, only a comparatively few can be presorted before delivery to a recycling plant. These few exceptions would include plastic milk and other beverage containers. Impressive research has been underway at Rensselaer Polytechnic Institute, and a patent has been obtained for a process that dissolves shredded plastics (as described by a researcher), "one polymer at a time in a chip-filled vat" where a solvent (xylene) is used to dissolve five groups of plastics at five separate temperatures, ranging from room temperature to 138°C (280°F). For example, polystyrene dissolves first, while the other plastics remain unaffected. The top solubility temperature required is well below the boiling point of the xylene solvent. As pointed out by the researchers, the xylene polymer solution (for a specific polymer) drains to a separate part of the system, where it is heated under pressure to near the boiling point of xylene. Pressure is required to keep the xylene-polymer solution in liquid form. The solution then is sent through a valve into a vacuum chamber to undergo flash devolitization. The sudden change from high to low pressure, researchers say, causes the xylene to vaporize instantly, leaving behind the pure polymer.

After the recovered polymer is removed, the same xylenes are recompressed and cooled to return to its liquid state. It again is heated to a different temperature and reintroduced into the vat to dissolve another of the polymers, and the interim steps are repeated until all polymers present have been separated.

Genetic Engineering and Pollution

Research on the genetic engineering of microbes to degrade toxic wastes has been underway for at least two decades. Progress has been relatively slow, partially attributed to societal concerns over the possible release of new, untested microorganisms that in themselves could create environmental and health threats. As one researcher in the field has pointed out, "No one wants to release organisms before the possible consequences are known, but the possible consequences will remain unknown until the organisms are released."

A very cautious approach has been taken thus far concerning the possible use of engineered microbes in connection with the Superfund dumpsite cleanup program. Budget allocations for genetic engineering in the pollution field have not exceeded a few million dollars annually for the past several years.

Pseudomonas putida, a common soil microbe, has been the target of several researchers. A few years ago, scientists at the University Medical Center (Geneva, Switzerland) created a microbe that eats 4-ethylbenzoate (4-EB), a toxic synthetic chemical. The researchers attempted to find all the "right" genes and combine them into one organism. As early as 1980, researchers in the United States designed a microorganism to break down crude oil. This also involved research with *Pseudomonas* bacterial species. Other engineered microbes have been created that break down much of the sulfur in coal. Research at Johns Hopkins University also has yielded engineered microbes that can metabolize sulfur.

Microorganisms have been used successfully to clean up contaminated wastewater of such substances as pentachlorophenols (PCPs), polychlorinated biphenyls (PCBs), iron cyanide, and leachates containing chlorinated compounds, phenols, and formaldehydes. A dry cleaning solvent, tetrachlorodiphenylethane (TCE), which is a suspected carcinogen, has been degraded through the use of enzymes released by a strain of the bacterium, *Pseudomonas cetacia*. A wastewater treatment plant has used a mutant strain of *Pseudomonas*, which consumes mine-generated cyanide wastes. A process has been developed that uses naturally occurring microbes to concentrate phosphorus for easy removal. It has been estimated that 99.3% of phosphorus in wastewaters can be removed by the process. One firm has developed a bioreactor that uses an aerobic microorganism (naturally occurring in white-roto fungus) to break down toxic substances, such as 2-chlorophenol.

Other researchers have designed a microorganism for breaking down crude oil, and some experience has been gained from testing the product for cleaning up oil tanker spills. Several proprietary engineered microbes have been announced, but with little detail given. Research firms in the field are delaying commercialization, pending clarification of federal, state, and provincial regulations. See also **Water Pollution**.

Fermentation. In 1990, a bioprocessing research center was opened at Penn State University. A pilot plant demonstrates various processes for converting (recycling) agricultural and food processing wastes into dietary supplements for animals. The pilot plant is designed with versatility and flexibility for testing and processing a wide variety of substances. One example of agricultural and livestock wastes that can occur during abnormal situations is an estimated 1 million tons/day of chickens that die of natural causes and are buried at a site on the Delmarva Peninsula, which borders on the Chesapeake Bay. In extremely hot weather, this figure can increase to 4 million tons/day. Also, it has been estimated that 600 tons/day of fish wastes are dumped off Kodiak Island. The Netherlands is estimated to produce 100 million tons/year of poultry manure, twice the amount that the land can absorb naturally. Researchers at Penn State have applied for patents on one of the fermentation processes developed. A type of marine yeast converts protein-bearing waste into a slurry of water-soluble proteins. The process destroys all pathogens. Thus, when the slurry is dried, it is suitable as a dietary supplement. Researchers note that the same principles could be applied to cesspool wastes. Although centralized sewer systems collect *un*sanitary wastes in most urban areas today, there remain multi-thousands or millions of cesspools used in less-populated areas of the country.

Recycling/Regenerating Paper Wastes

Considerable progress has been made during the past decade for recycling paper wastes, which according to Table 4 constitute well over one-third of the typical municipal waste produced.

Investigators at Texas A&M University (Austin, Texas) are targeting on improved processes for regenerating paper wastes. One of the key problems is the cellulose content in newspapers and paper products. Cellulose is very difficult to "digest." The researchers have developed an ammonia fiber explosion (AFEX) technique that more efficiently utilizes enzymatic digestion of cellulose. Researchers explain that ground-up municipal waste is placed in a tank and soaked with ammonia for about one-half hour, after which high pressure is applied. When this pressure is released abruptly, cellulose fibers are literally blown apart, making it much easier for enzymes to digest them. The enzymes break down the cellulose into individual glucose molecules, after which yeast can convert them to ethanol. The researchers have noted an improvement of up to 150% in digestion as the result of the AFEX process. Researchers also forecast that 180 billion tons of municipal wastes could be converted into over 8 billion gallons of ethanol fuel for automotive consumption.

In many communities, prescribed routines for consumers to separate paper from other items of trash have been highly successful and, in fact, in recent years there has been more paper ready to recycle than there are

facilities to process it. Consequently, a lot of newsprint and other paper products still go to the dumpsite. Paper in the household trash is a highly visible waste to the average consumer—hence, much cooperation from the populace has been evidenced. In recognition of an imminent "glut" of newsprint to recycle, some municipalities and states have lowered their targets. One example is Wisconsin, which had set a goal of 50% recycled fiber by 1995 to 17% by 2001.

As mentioned earlier in this article, there is a continuing conflict (triangle) of forces that come into play in numerous decisions that interlock the factors of energy, environment, and economy. Newsprint as of the early 1990s is an example. Publishers, particularly in the northeastern United States, can obtain paper of high quality and made of virgin fibers from nearby Canada at an attractive cost, not much in excess of the cost of recycled newsprint. Canadian paper is imported duty-free. Approximately 58% of the paper consumed in the United States (overall) is imported from Canadian mills from trees grown in Canada. Expected lower timber prices in the southeastern United States may make that region more competitive with Canada over the next decade or two.

Average use by newspapers of recycled fibers seldom exceeds 50% of the total. However, the publishers of the *Los Angeles Times* use approximately 80% recycled fiber.

Recycled newsprint does pose problems to publishers, notably those of books and magazines. Some virgin pulp is required to hold the paper together. Magazine publishers usually purchase what recycled paper they do use from pulp-substitute suppliers—that is, firms that process only selected used paper, such as envelope trim and cuttings, ledgers, business forms, and computer printout paper. A long-range recycling program also poses the problem of dealing with shorter fibers. Each time paper is reprocessed, the fibers are shortened. The present use of recycled fiber in newspapers is, on the average, about 20%.

The processing of recycled paper is essentially the same as the production of paper from virgin fibers once the feed slurry is made. See article on **Papermaking and Finishing**; and **Pulp (Wood) Production and Processing**.

In preparing the slurry for recycled newsprint, first all trash must be removed from the waste paper (some manual labor assisted by machine metal detectors, etc.). The paper then passes to a pulper, where water and some reagents are used to accomplish de-inking. In the pulper, the waste paper is shredded by rotating cutting blades to produce a slurry. This slurry is passed through a continuous pulper, similar to that used in making virgin paper slurry after the natural fibers have been processed in a digester. The slurry then passes through screens and onto a three-stage washer, where ink particles are fully removed and the paper adjusted for the proper consistency prior to being introduced onto the paper machine.

Considering the numerous errors that have appeared in the environmental literature, Stephen Strauss, a science writer for the *Toronto Globe and Mail*, points out how easy it is to draw conclusions regarding environmental measures when raw data have not been gathered, calculated, or presented with exacting care. Strauss makes the serious but amusing observation, "When historians of technology reflect on the final quarter of the twentieth century, they may well surmise that the archetypal public debate (over pollution) centered around the throw-away (paper or foam) cup."

See Strauss reference listed.

Several other articles in this encyclopedia address the topic of waste and pollution. See also **Pollution (Air)**; **Water Pollution**; and alphabetical index.

WASTES AS ENERGY SOURCES. Initially, *biomass* was defined as the amount of living organisms in a particular area, stated in terms of the weight or volume of organisms per unit area or of the volume of the environment. This definition still applies very well to ecological and geophysical assessments of land areas or regions and depths of the seas and lakes.

In modern technology, the term also may be used to describe the exploitation of living terrestrial materials, such as plants or marine plants, all or parts of which may be combusted directly for the thermal energy that they yield or, more indirectly, as raw materials for processes that can convert the biomass into fuels.[1] Very generally, biomass may be considered the total amount of living matter within a given unit of area, volume, or mass. When biomaterials serve as foods or provide fibers and items of construction, for example, waste is created. These materials are typified by straw, sawdust, sewage sludge, and so on, which possess value as energy sources. That aspect of biomass is the topic of this article.

Generally, the pace of research and construction of facilities for transforming solid wastes into energy forms, such as methane, or to recover heat from combusting the wastes, slowed during the late 1980s and early 1990s. There are several causative factors, but of course a breakthrough could reverse these trends. In the 1970s, during the time of the oil embargo and energy crisis, finding new sources of energy was a major incentive. The fervor of the former energy programs has largely deteriorated in the presence of what is now considered by many a severe environmental crisis. This latter incentive has not been sufficient to foster extensive research programs in transforming garbage and other trash into energy because the *primary* advantages remain as an energy source and not as a means of pollution abatement. Nevertheless, progress has been made. Simply combusting municipal rubbish as a means of waste disposal is described in the preceding article.

Considerable research is being conducted on a variety of biomass feedstocks that contain cellulose, from which ethanol can be produced. Again, ethanol as a transportation fuel component has not been widely accepted, even though aggressively promoted in some areas. Brazil usually is cited as a prime example of progress in this area. L.R. Lynd (Dartmouth College) and a team of researchers have been studying the impacts of alternative fuel use on carbon dioxide (CO_2) accumulation, energy security, and economic effects on the United States as a whole. The team observes, "Production of ethanol from cellulosic biomass is believed to be an emerging energy technology with particularly great potential for the U.S. transportation sector. Research to improve conversion processes and to develop cellulosic energy crops is necessary to reduce costs and to increase production potential. Success can reasonably be expected in both these areas in light of the immature state of current technology and the powerful approaches available." In terms of their potential for yielding ethanol, in order of diminishing production potential, are agricultural wastes, forest sources, and municipal solid waste.

The majority of agricultural, commercial, industrial, and urban or municipal wastes are of a biological rather than mineral nature and thus fall under the umbrella of biomass. The simple burning of wood for heat illustrates one of the simplest ways to convert biomass to energy. All biomass represents an indirect form of solar energy. Biomass, as a source of energy, differs from coal, natural gas, and petroleum in one major way—biomass is renewable. Some potential biomass energy crops can be renewed as frequently as two or three times per year, depending upon location, while other materials such as trees have a renewable cycle of several years. Anthropogenic wastes are renewed on a daily basis. Interest in biomass over the last several years has stemmed from the overall concern with ultimate exhaustion of nonrenewable energy sources, as well as gaining a degree of political independence by many nations that either do not have any fossil fuel resources, or that have insufficient supplies to maintain a strong economic and industrial position.

Urban Wastes as Energy Sources

Urban waste includes household, sewage, commercial, institutional, manufacturing, and demolition waste. The availability of this waste is directly related to the population living in urban areas of adequate size to support a given size system.

Manufacturing and processing wastes include all residuals generated from material inputs that leave the plant as product output. Office and packaging wastes associated with this sector are included in the urban waste sector. The majority of these wastes are from pulp and paper manufacturing, primary and secondary wood manufacturing, and the construction industry.

The energy recovery system selected dictates the extent that solid waste must be prepared. Some systems require nothing more than the removal of massive noncombustibles, such as kitchen appliances from the refuse, while other processes require extensive shredding, air classification, reshredding, and drying. In conjunction with fuel preparation, it is usually worthwhile to reclaim metals and glass for recycling.

One-stage shredding is often used to reduce waste to a nominal size as small as 1 inch (2.5 centimeters). When finer-sized fuel is required, a second shredding step is usually used after air classification has removed many of the noncombustibles. Both vertical and horizontal air classifiers depend on the heavy noncombustibles settling out by gravity in a moving air stream, while the lighter combustibles are pneumatically transferred through the air classifier. Denser combustibles, such as rubber and leather, may be removed with the heavy fraction, while some of the fine glass and metal foils are carried with the combustibles. Thus, desired separation may not always be achieved on one pass through an air classifier.

Some energy recovery systems require drying to remove excess moisture in the waste. This is required when sewage sludge is used as a fuel. Usually, waste heat from the total process can be used for the drying system.

Pyrolysis. In one system, municipal refuse is charged at the top of a shaft furnace and is pyrolyzed as it passes downward through the furnace. Oxygen enters the furnace through tuyeres near the furnace bottom and passes upward through a 1425 to 1650°C combustion zone. The products of combustion then pass through a pyrolysis zone and exit at about 93°C. The off-gas then passes through an electrostatic precipitator to remove flyash and oil formed during pyrolysis. The latter are recycled to the furnace combustion zone. The gas then passes through an acid absorber and a condenser. The clean fuel gas has a heating value of about 300 Btu/cubic foot (2670 Calories/cubic meter) and a flame temperature equivalent to that of natural gas. The solid waste that remains is a slag at the furnace bottom.

Biological Methane Production. This process involves the anaerobic digestion of a solid waste and water or sewage sludge slurry at 60°C for five days to produce a methane-rich gas. Solid waste is prepared by shredding and air classification, followed by blending with water to produce a mixture of 10 to 20% solids concentration. The slurry is heated and placed in a mixed digester at 60°C for 5 days detention. The digester gas is drawn off and separated into carbon dioxide and methane. The spent slurry from the digester is pumped through a heat exchanger to partially heat the incoming slurry prior to filtration. The filtrate is returned to the blender and the sludge is used for landfill. Heat addition to the refuse slurry is required to maintain the required digester temperature. The process is well suited for use on sewage sludge, animal manures, and other high-moisture-content solid wastes. It is estimated that the process can reduce the volume of volatile solids by 75%, while producing about 3000 cubic feet (85 cubic meters) of methane per ton of incoming solid waste. The major residue is used for landfill or incinerated. About 10% of the methane is required to heat the digester feed.

Direct Steam Process. One process uses a rotary kiln pyrolizer followed by an afterburner and boiler to produce steam from shredded waste. The pyrolysis process in a kiln is operated countercurrently. Solid waste enters at one end and pyrolyzed residue is discharged at the other. External fuel and air are introduced at the residue discharge area and combustion products and pyrolysis gases leave the kiln at the feed opening. This arrangement causes the solid waste to be exposed to progressively higher temperatures as it passes through the kiln. The kiln off-gases pass through a

[1] The generation of biomass from carbon dioxide is called "primary production" because it is the first fundamental step in turning inorganic material into organic compounds and cell constituents. This reduction of carbon dioxide uses sunlight as the source of energy. See also **Photosynthesis**.

refractory-lined afterburner into which air is introduced to allow complete combustion prior to passing through the waste heat boiler. A wet scrubber is used for air pollution control, while an induced draft fan is used to draw the gases through the system. One ton of solid waste, augmented by 1.25 million Btu (0.3 million Calories) from auxiliary fuel and 55 kilowatt-hours of electricity will produce about 4800 pounds (2177 kilograms) of steam at 330 psig (22.4 atmospheres) along with 200 pounds (91 kilograms) of char.

Waterwall Incinerators. These devices generate steam by burning unprepared solid waste on a grate and passing the hot products of combustion through a boiler. Numerous waterwall incinerators have been built in Europe and the United States. Unprepared refuse is taken from storage pits and charged directly into the incinerator feed hopper. From there, the refuse drops onto a feed chute and then is fed automatically onto the stoker by means of a hydraulic feed ram. Temperatures in the 870°C range effectively burn the solid waste. Before the flue gas enters the boiler, secondary air is added to produce a temperature near 1090°C. The boiler is constructed of membrane waterwalled tubes with extruded fins. After passing through the boiler, the gases travel through an economizer section and then into an electrostatic precipitator for particle removal. A typical 1000 tons/day (900 metric tons/day) waterwall incinerator produces about 300,000 pounds (136,080 kilograms) of steam per hour.

Additional engineering is required where toxic wastes may be present.

Principal Biomass Materials for Energy

Biomass-to-energy systems fall into two principal categories: (1) materials for direct combustion that will generate heat for processing, for warming living and working spaces, for steam and hence also for generating electricity; and (2) materials from which both fuels and chemicals can be obtained through biochemical or thermochemical conversion processes. Resulting fuels must have ample caloric content per unit of weight and thus rich in carbon and hydrogen and poor in the content of atoms, such as oxygen and nitrogen, which do not contribute to the caloric value of the fuel. In searching for new biomass raw materials, scientists have found it helpful to study the various biosynthetic pathways followed by plants from seed to maturation.

Direct Wood Burning. Wood was the major fuel of the United States until about 1886 when the consumption of coal equaled that of wood. Oil did not appear on the chart until about 1900 and gas in 1910–1920. The use of wood tapered off while other fuels climbed at amazing rates, but wood never ceased as a factor, even if small. It is interesting to note that about a million modern woodburning stoves are in use and that about 40% of the wood products industry is furnished by combusting bark and mill wastes. This amounts to about 1 quad (10^{15} Btu). Wood burning has been sufficiently extensive during the past few years to cause environmental concerns in some regions. Although wood has a low sulfur content and produces minimal amounts of nitrogen oxides even by the hottest fires (1370°C; 2500°F), it contains air pollutants in the form of particulates, gases, and tars. Environmentalists in the New England region have estimated that the 300,000–400,000 tons of wood burned per year (New Hampshire only), if the fuel is very dry red oak, will add 1000 tons of particulates to the air; if dry white pine is burned, the total may be over 5000 tons. Since a mixture of woods usually is used, the figure lies somewhere between the two aforementioned quantities.

Agricultural Wastes. In the absence of an energy crisis, with a few exceptions, attention to the use of agricultural wastes has waned. These materials continue to represent an essentially untouched source of energy in most countries. In the course of extensive scientific research in the early 1970s, at a time when renewable energy sources were being aggressively sought, evaluations were made of various materials for their caloric content and availability. Included were corn (maize), sorghum, wheat, sugar beats, sugarcane, pineapple, and cassava, among others. Several of these crops were considered as sources for the production of alcohol for admixture with gasoline (gasahol) as an automotive fuel. Brazil has had considerable success in this regard with sugarcane as a raw material.

Although burning and incineration offers means for disposing some waste products, these processes do contribute to air pollution and thus must meet the requirements now followed for the common fossil fuels.

WATER. A colorless (blue in thick layers) liquid, H_2O or HOH, odorless, tasteless, melting point 0°C (one of the standard temperature points), boiling point 100°C at 760 millimeters of mercury pressure (another standard temperature point).

The boiling point of water increases with increasing pressure: 100.366°C at 770 mm; 120.6°C at 1,520 mm; 180.5°C at 7,600 mm. The boiling point decreases with decreasing pressure: 99.360°C at 750.0 mm; 99.255°C at 740.0 mm; 98.877°C at 730.0 mm; 81.7°C at 380 mm; 46.1°C at 76.0 mm.

At 0°C, the density of water is 0.99987 gram per milliliter. At 8°C, 0.99988; at 15°C, 0.99913; at 16°C, 0.99897; at 17.5°C, 0.99871; at 20°C, 0.99823; at 25°C, 0.99707; at 40°C, 0.99224; at 50°C, 0.99807; at 75°C, 0.97489; at 100°C, 0.95838; at 120°C, 0.9434.

The critical temperature of water is 374.15°C; critical pressure, 218.4 atmospheres; critical density, 0.323 gram per cubic centimeter.

The viscosity at 0°C is 0.01792 poise (dyne second per square centimeter), specific viscosity, 1.000. At 20°C the viscosity is 0.01005 poise, specific viscosity, 0.561. At 50°C, the viscosity is 0.00549 poise, specific viscosity, 0.307. At 75°C, the viscosity is 0.00380 poise, specific viscosity, 0.212. At 100°C, the viscosity is 0.00284 poise, specific viscosity, 0.158.

The surface tension of water against air at 0°C is 75.6 dynes per centimeter. At 10°C, the surface tension is 74.22; at 20°C, 72.75; at 30°C, 71.18; at 60°C, 66.18; and at 100°C, 58.9.

The specific heat of water is 1.000000 at 15°C (standard of specific heat). At 0°C, the specific heat is 1.00874; at 25°C, 0.99765; at 35°C, 0.99743 (minimum); at 50°C, 0.99829; at 65°C, 1.00001; at 80°C, 1.00239; at 100°C, 1.00645; at 120°C, 1.016; at 180°C, 1.04.

The electrical conductivity of water at 18°C is 0.04×10^{-6} reciprocal ohms (measurements of Kohlraush and Heydweiller, 1902); of pure water in equilibrium with air, 0.8×10^{-6}; of ordinary distilled water, about 5×10^{-6}.

The dielectric constant of water (specific inductive capacity) is 81.07 at 18°C.

Pure water, when free of dissolved gases, may be heated above 100°C (even up to 180°C) without boiling, but upon further heating, boiling with explosive violence may occur. Steam at 100°C occupies a volume 1,700 times greater than water at 100°C. Pure water, when not agitated, may be cooled somewhat below 0°C without freezing, but upon further cooling it congeals with an increase of volume (density of ice, 0.917) exerting great force, when confined, but if in intimate contact with water at atmospheric pressure, the freezing temperature is 0°C. The vapor pressure of ice and water is 4.579 millimeters at 1 atmosphere pressure and 0°C. The triple point (ice, water, and water vapor) occurs at a saturation vapor pressure of 6.11 millimeters and at a temperature of 273.16 K. When water is compressed to about 20,000 atmospheres and then cooled, other varieties of ice, all denser than water, are formed. Ice II is 12% denser; Ice III is 3% denser. At least six varieties of ice are known.

In ice I, ice II, and ice III, each oxygen atom is surrounded tetrahedrally by four other oxygen atoms, the difference between the three forms being largely in some distortion of the linkages, since the O—O distance varies little from the 2.76 value of ice I. Each oxygen atom has 2 hydrogen atoms

quite close (about 1 Å) to it. At lower temperatures, and presumably higher pressures (forms V, VI, and VII, the water molecules with four hydrogen bonds are more in evidence.

Liquid water exhibits the same tendency toward increased bonding at lower temperatures. While individual water molecules have a nonlinear structure, there is association between H_2O molecules by hydrogen bonding, the degree of association being greater at lower temperatures. Based upon the statistical mechanical treatment of Frank and Wen, liquid water may be regarded as a mixture of hydrogen bonded clusters and unbonded molecules. Other research characterizes this model in terms of 5 species: unbonded molecules, tetrahydrogen bonded molecules in the interior of cluster; and surface molecules connected to the cluster by 1, 2, or 3 hydrogen bonds.

The chemical properties of water change with temperature at high temperatures. The reaction, $2H_2O \longleftrightarrow 2H_2 + O_2$, shows an appreciable shift to the right, reaching 0.8% at 2,000°C, and increasing rapidly above that temperature. At ordinary temperatures, the equilibrium, $2H_2O \longleftrightarrow H_3O^+OH^-$, is important because it enables water to act either as a proton donor or acceptor. With stronger acids, water can act as a proton acceptor:

$$HCl + H_2O \longleftrightarrow H_3O^+ + Cl^-$$

$$HBr + H_2O \longleftrightarrow H_3O^+ + Br^-$$

$$HSO_4{}^- + H_2O \longleftrightarrow H_3O^+ + SO_4{}^{2-}$$

With stronger bases, water can act as a proton onor:

$$H_2O + CO_3{}^{2-} \longrightarrow HCO_3{}^- + OH^-$$

$$H_2O + NH_3 \longrightarrow NH_4{}^- + OH^-$$

Although the ions shown are written as $CO_3{}^{2-}$, $HCO_3{}^-$, Cl^-, etc., they of course are more or less solvated by the water, i.e., they have water molecules attached to them by ion-dipole bonds, since water is a polar compound. One of the most strongly marked properties of water is its behavior as an electrolytic solvent, which is due to its high dielectric constant. The energy of separation of two ions is an inverse function of the dielectric constant of the solvent. Some of the parameters of water are shown in diagram of Fig. 1.

Molecular Architecture

Greatly oversimplified, the water molecule may appear as shown in Fig. 2, which indicates the equilibrium position of the oxygen atom and the hydrogen atoms, i.e., the equilibrium position of the positive and negative charges of the molecule. Because of this orientation, the water molecule has a strong tendency to be oriented in an electrical field. The dipole moment depends upon the magnitude of the charge separation within the molecule, and in the water molecule, the separation is large. Thus, water may be described as having an exceptionally large dipole moment and consequently a large dielectric constant. On the basis of ascribing a dielectric constant of 1 for a vacuum, the dielectric constant of water is 80; i.e., in water, 2 electrical charges will attract or repel each other with only 1/80th as much strength as would be the case in a vacuum. This accounts, at least in part, for the remarkable ability of water to dissolve substances, particularly materials whose molecules are held together primarily by ionic bonding.

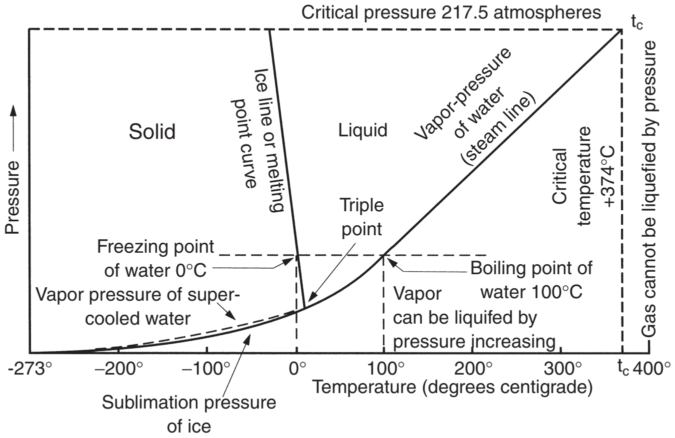

Fig. 1. Pressure-temperature diagram for water

The bonding arrangements within the water molecule also account for the exceptional cohesive power exhibited in water's high surface tension and the outstanding ability of water to adhere strongly to a variety of materials (the property of wetting). Bonding also accounts for the manner in which water crystals, e.g., snowflakes, are formed and for the maximum density of water (4°C), below which water assumes less dense forms, causing ice to float. Bonding is responsible for the exceptional heat capacity and exceptionally high latent heats of fusion and evaporation of water.

The molecular behavior of various molecular types in electrolytes is shown in Fig. 3. This behavior is of particular significance to the role of water in biological systems. See also **Molecule**.

Although of continuing interest, research on the structure of water is exceptionally difficult. X-ray crystallography has provided a good picture of the stable hydrogen-bonded structure of ice, but thus far the structural imaging of liquid water has escaped investigators, and hence blackboard theorizing and computer modeling are the principal research techniques followed. In the *Journal of the American Chemical Society* (*JACS*) of May 20, 1992, water scientists present a complex new theory that may account for so many of the physical properties of liquid water.

Heavy water, also known as deuterium oxide, D_2O, is water in which the hydrogen of the water molecule consists entirely of the heavy-hydrogen isotope having a mass number of 2. The density of heavy water is 1.1076 at 20°C. Heavy water has been used as a moderator in nuclear reactors as well as a coolant.

Uses

Water is such a common substance that its importance and versatility are usually taken for granted. Included among the major ways in which water is important would be: (1) as a raw material for incorporation into final products without chemical change; (2) as a raw material for undergoing chemical change; (3) as a transport and conveyance medium with water acting as a solvent or carrier of solutions and suspensions in and out of reactions and physical-change operations—at an industrial as well as biochemical level; (4) as a heating and cooling medium over the wide temperature range from below normal freezing temperature (brine solutions, for example) to those of superheated steam; (5) as an energy-storage medium; (6) as a gathering medium for waste products; (7) as a cleaning medium; (8) as a shield against heat and nuclear radiation (heavy water); (9) as a convenient standard in terms of temperature, density, viscosity, and other units; and (10) with exception of a few situations where the presence of water is hazardous, as a fire-fighting medium.

Water Metabolism in Vertebrates

Those vertebrates that now inhabit land, seas, brackish and fresh waters have survived because they have developed homeostatic mechanisms that enable them to cope with considerable variation in the content and availability of water, sodium, potassium, and chloride in their external environment. These mechanisms prevent life-threatening changes in their internal environment by (1) assuring that the cells are bathed by fluid with the same osmotic concentrations as themselves; and (2) by preventing major qualitative changes in the intra- and extracellular content of these ions or water. Regardless of species, one is impressed not by the differences, but by the similarities in the ionic composition of their intra- and extracellular fluids. The water content of the fat-free tissues of all vertebrates ranges between 70 and 80%. Water diffuses freely along its concentration gradient (osmosis) throughout all body tissues. Therefore, any deviation of the osmotic pressure of intra- or extracellular fluids, by either withdrawal or addition of water, causes an immediate movement of

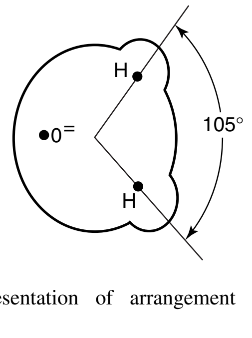

Fig. 2. Schematic representation of arrangement of electrical charges in water molecule

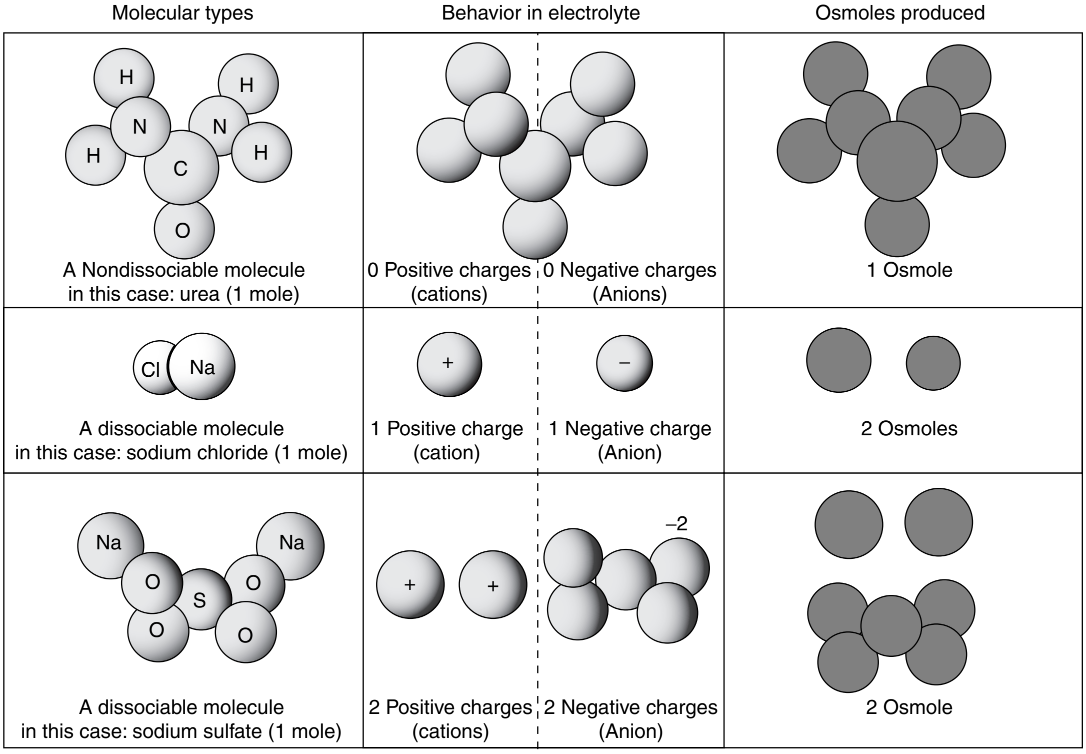

Fig. 3. Behavior of various molecular types in electrolytes. (*After Maffy.*)

water from the more dilute to the more concentrated solution until osmotic equilibrium is reestablished.

Water is lost from the body of mammals by evaporation across the skin and in the expired air, urine, and feces. The more arid the environment, the more a mammal must be able to reduce water loss and tolerate longer periods of water dehydration and hypertonicity of its body fluids.

According to Chew, vertebrates fall into several groups in terms of how they maintain their water balance. *Fishes and amphibians* in fresh water are very hypertonic to their medium and must counteract a continual dilution of their body fluids. Water influx is reduced by the relative impermeability of the skin, and is balanced by diuresis. Electrolytes lost in this urine are replaced in food eaten and by absorption through gill surfaces (fishes) and skin (amphibians). *Marine elasmobranches* are unique in maintaining themselves slightly hypertonic to sea water by retention of urea (2±%) in their body fluids, making their osmotic pressure more than twice that of marine teleosts. *Marine teleosts* and terrestrial tetrapods face the continual problem of counteracting desiccation due to osmotic loss to a hypertonic medium or to evaporation. Mammals are the most effective of vertebrates in conserving urine water by concentrating the urine, which is achieved by reabsorption of water in the kidney tubules.

Terrestrial tetrapods adjust by avoidance of evaporative stress, reduction of evaporative and urinary water losses, and temporary toleration of hyperthermia or hypernatremia. Antidiuretic hormone (ADH) from the neurapophysis is very important in enhancing uptake of water through the skin (amphibians), reduction in glomerular filtration (amphibians, reptiles, birds), and increase in tubular reabsorption of water (mammals).

Water balance processes are best developed in species inhabiting deserts, where little drinking water is available and climatic conditions accentuate evaporation.

Certain toads and frogs survive in deserts, needing open water only for breeding, largely by remaining dormant during dry periods. Evaporation is greatly retarded in a cool damp burrow, and urine volume is reduced by 98–99% (filtration antidiuresis), but urine remains hypotonic. Urinary water may be recycled through the body by reabsorption from the bladder. Dormant animals tolerate a loss of 50–60% of their body water. They emerge during rains, and in their dehydrated state quickly reabsorb water through the skin.

Terrestrial reptiles also avoid considerable evaporation by being quiescent in burrows much of the time. Also, their skin is more impermeable than that of amphibians, although water is still lost in expired air. Hydrated lizards have low urine filtration rate (urine always hypotonic), and may become almost anuric when dehydrated. During dehydration, electrolyte wastes are retained in the body and tolerated in concentrations fatal to birds and mammals, until water is available for their excretion. A carnivorous diet (70±% water) provides adequate water intake while food is available. Water can be reabsorbed osmotically from the cloaca, reabsorption being particularly effective because of the nature of the principal nitrogenous waste, uric acid, which has a very low solubility. As uric acid precipitates in the cloaca, its osmotic effect is removed, and further water can then be absorbed by osmosis. This is probably the major value of uric acid excretion. Precipitated wastes are excreted en masse, with very little fluid loss.

Birds, being homeothermic, cannot reduce their evaporative loss by becoming dormant. Being diurnally active and exposed to radiant energy, they must often expend water for cooling, by panting. Consequently, in arid regions the distribution of birds is limited to areas within flying distance of water. Some water expenditure is avoided by allowing hyperthermia (up to 3°C) in the daytime.

Desert rodents lead the most water-independent life of all vertebrates. Kangaroo rats can so reduce their evaporation that they are able to maintain water balance on only metabolic water. Other species survive on only metabolic water plus free water in air-dry seeds. Respiratory water loss is reduced by cool nasal mucosal surfaces, which condense water from warm air coming from the lungs, before it can be expired. Skin impermeability involves a physical vapor barrier in the epidermis, plus unknown physiological factors.

Many larger mammals are exposed to daytime radiant energy and need to dissipate heat by sweating, panting or wetting themselves with saliva (marsupials). These water expenditures must be balanced periodically by drinking. A dehydrated camel is particularly physiologically adapted to store heat (rather than dissipate it by evaporation), undergoing a temperature rise of up to 6° in the daytime.

Water in the Human Body

The adult male human body contains about 60% (weight) of water and the adult female body about 50%. The large amount of body water is compartmentalized, each compartment being bounded by membranes. It has been estimated (Edelman and Leibman, 1959) that 55% of this water is contained within cells and that it is bounded by cell membranes. The remaining, extracellular water or fluids (ECF) is made up of a relatively small volume of plasma (7.5% of total body water in the vascular tree), with the remaining 37.5% in nonplasma and located outside the vascular

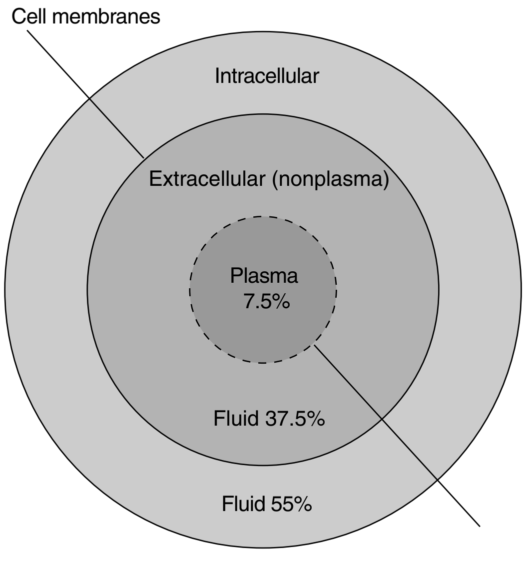

Fig. 4. The three principal categories of body water

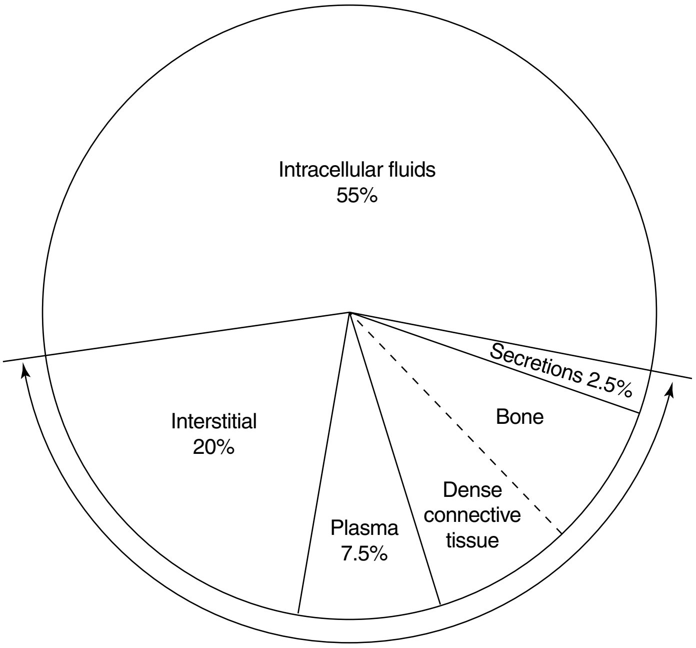

Fig. 5. Pie chart showing approximate volumetric proportions of body fluids

tree. The latter includes interstitial water (20%), another 15% in bone and dense connective tissue, and 2.5% in secretions. These numbers are shown graphically in Figs. 4 and 5.

Two driving forces control the movement of water in the body, namely, hydrostatic pressure and osmotic pressure. Because transmembrane pressures are so low, it is not believed that hydrostatic pressure plays a role in the movement of water across cell membranes. On the other hand, hydrostatic pressure resulting from heart action creates a gradient of about 20 millimeters of mercury pressure across the capillary walls. The principles of osmosis are described in the entry on **Osmotic Pressure**. Normally, in describing osmotic pressure, reference is made to salt solutions of differing concentrations separated by a membrane. Concentrations are expressed in terms of solute in solvent (water). When thinking in terms of body water, one usually considers the addition of solute to the water as a dilution of the pure water rather than as an increase in solute content of the water. For example, pure water contains 55.5 moles per kilogram (about 55,500 mmoles/liter). Body fluids, that is, intracellular fluid (ICF) and extracellular fluid (ECF) contain approximately 99.5% water molecules and 0.5% solute molecules. This equals about 55,200 mmoles of water per liter; and 300 mmoles of solute per liter. Osmolality is a measure of the concentration of osmoles present in the water. If the osmolality is low, the concentration of water is high; if the osmolality is high, the concentration of water is low. Movement of water across the cell membranes occurs because of differences in concentration, the movement always being from a phase of high water concentration to one of lower concentration. Movement is "downhill" so to speak and the motivating force is called osmotic pressure. This movement can be counteracted by the application of an opposing force, notably hydrostatic pressure.

It is interesting to note that the main cation present in ICF is the potassium ion, whereas the principal cation in ECF is the sodium ion. The role of potassium and sodium ions in the biological system is described in the entry on **Potassium and Sodium (In Biological Systems)**.

Water Intoxication. Either an increased intake of water or a decreased output of water can cause an excess of body water. Because healthy kidneys have outstanding ability to increase water excretion, a condition of water intoxication usually occurs because of a disability to excrete water (*hyponatremia*). Frequently impairment may not be the result of disease or damage to the kidneys per se, but rather due to faulty processing of stimuli by the kidneys. Excessive renal reabsorption of water can result from the action of antidiuretic hormone (ADH) or by the excessive reabsorption of sodium in the proximal tubules. Under such conditions, the excretion of water and sodium will be low. Retention of salt and water causes an expansion of the ECF, usually resulting in edema and effusions.

Water Deficiency. This condition occurs when water output exceeds intake. Water is continually lost by way of the lungs, skin, and kidneys and thus a deficiency of body water will occur if a critical minimal supply is not maintained. Decreased intake when water is available is uncommon. Very rarely, a brain malfunction may interfere with one's sense of thirst. Increased output of water can result from many causes. For example, a person with diabetes insipidus who lacks ADH (antidiuretic hormone) or a person whose kidneys do not respond normally to ADH, as in instances of nephrogenic diabetes insipidus, will increase water output. Other diseases which may cause excess excretion of water include osmotic diuresis, hypercalcemia, hypokalemia, chronic pyelonephritis, and sickle cell anemia, among others. Excessive water losses are also experienced in some cases with advanced age and in some burn cases. Two clinical features are good measures of dehydration—weight loss of the patient and an elevation of the serum sodium concentration. In situations of dehydration, the body initiates mechanisms which manipulate the transfer of water from one compartment to the next, retaining water in those cells and organs where it is most needed.

In cases of severe dehydration, rehydration must be brought about carefully and in steps. The usual practice is to make an initial estimate of water or electrolytes that require replacement and then to administer one-half the amount of the deficit, after which another series of measurements is made, followed by replacement of one-half of the estimate—until a satisfactory ultimate balance has been attained. If rehydration is not gradual, some organs, such as the brain, may take up water beyond normal requirements and this can result in cerebral edema. Also, in the case of acute dehydration, permanent brain damage can occur as the result of a shrinking brain tearing away vessels, causing cerebral hemorrhages.

Water and Macromolecules

Over eons of time, processes have appeared for making the great variety of macromolecules required by living organisms. Most of these developments have occurred in a water medium, or in one having a high water vapor content. So it is not surprising that the majority of the macromolecules involved in the life processes are hydrophilic, in different degrees. One may find minor exceptions in the cases of certain fats and lipids. It should be noted that in living organisms, the hydrophilic macromolecules of one kind often join with those of other kinds to produce the useful structures required in the life process, i.e., membranes.

Decades ago, biochemists recognized that it was difficult to remove all water from a large number of macromolecular materials. The term "bound water" was coined to explain the great affinity many of these materials showed for water, particularly the proteins. Biochemists were convinced that biological behavior, at least in part, resulted from the amount of "bound water" contained in the macromolecular structure. As an example, water held in plant structures so that it did not freeze in below-freezing temperatures was considered to be bound. At the time these ideas found favor, the method of lyophilization or quick freeze-drying had not been

perfected. Lyophilization removes the bulk of the water held in biological substances without destroying their structures or their activity.

In more recent years, lyophilized proteins have been further dried to a constant weight in a high vacuum and then studied as they adsorbed water vapor. The heats of adsorption of the first water vapor molecules were considerably higher than the values obtained as the adsorption approached that of the saturated vapor. These results indicated that the first molecules to be adsorbed were on the most water-loving or active sites. Such adsorbed molecules on the higher-energy sites would be desorbed last in a high vacuum. Without going into considerable detail, the results of this line of research led to the conclusion that the earlier concept of "bound water" was unfounded.

Many biological systems depend in part on their degree of hydration. Most biological membranes are hydrophilic, but should the membrane be a multi-layered one, the hydration of the different layers may well differ markedly. A great many of the membranes used by living organisms are known to be selective in what passes through them. For many years the theory of the role of some membranes in pumping water into the cells they surround even against high osmotic gradients due to salt concentration has maintained among most biologists. The fascinating field of membrane biophysics has shed much light concerning the hydration of biological macromolecules.

As pointed out by Kolata, a primary difference between living and dead cells is that living cells selectively retain certain ions, such as potassium, and exclude others, such as sodium. The water in dead cells reflects the conditions of the solution around them. The conventional explanation is that this difference is due to ion "pumps" in membranes, pumps purported to use cell energy to transport some ions into and other ions out of the cell. There is another school of thought, however, which denies that such pumps exist. This school claims that ions are excluded from cells on the basis of their low solubilities in cellular water, except when specific charged sites with which the ions can associate are available. It is maintained that cell water has a different structure than either liquid water or ice and that it is this special structure that affects the solubility of various ions in it. This school also suggests that there is evidence that ion pumps are thermodynamically impossible, requiring more energy than is available to the cell. The school also claims that nuclear magnetic resonance (NMR) studies show that cell water is more structured than liquid water and less structured than ice. This, it is believed, would affect the solubilities of ions in the cell and could account for selective ion exclusions. A number of investigators, including advocates of pumps, have agreed that cell water may have some ordered structure that makes it different from liquid water. Most investigators do not question that cell water is likely to be structured, but do ask to what extent it is structured and what the physiological importance of this structure may be.

Degassed Water. It is interesting to note that during the past several years, Russian scientists have raised some intriguing points concerning water, not all of which have held up under intensive scrutiny. Some readers may recall the discussions of the early 1970s concerning the "discovery" of polywater or so-called anomalous water by some Russian scientists. Observations of this water did not meet with accepted criteria for physical properties. For a while, it was considered by some scientists to be of a polymeric nature, but as the result of subsequent numerous exchanges of views and a careful scrutiny of the water it was found to be ordinary water which had a large concentration of dissolved minerals.

In 1978, other Russian scientists proposed that meltwater (from freshly melted snows) carries certain biological properties not known in ordinary water. The Russian scientists theorized that meltwater retains some of the order that is characteristic of frozen water and that this increased order alters vital reaction rates within cells. This tends to tie in with the concept of structured water discussed briefly later.

In the course of investigation at the Institute of Fruit-Growing and Vine-Growing (Kazakhstan, Russia), investigators tested the relative growing rates, qualities, and yields of various plants subjected to meltwater, tap water, and boiled water. Although the plants responded in a superior way to the meltwater, as compared with tap water, it was found (more or less accidentally) that the plants responded even better to quickly cooled boiled water. Thus, the experimenters concluded that the superior action on plants derived from the fact that some of the waters tested (meltwater and quickly-cooled boiled water) contained less dissolved gases. In other words, the claim was made that any degassed water is superior when administered to plants. Igor Zelepukhin suggests that the conductivity of degassed water is decreased considerably and there are comparative increases in density, viscosity, surface tension, energy of intermolecular interaction, and internal pressure, factors that may enhance the value of water. Zelephuhkin thus observed further that degassed water bears a closer resemblance to the fluid in cells than does ordinary tap water. Experiments in utilizing degassed water for cattle and livestock are proceeding. Other Russian investigators have observed that concrete prepared with degassed water is from 8 to 10% stronger than when ordinary water is used. It should be stressed that, as of the early 1990s, these observations have not as yet been accepted by the general scientific community. Considerably more research is required toward the development of hard, convincing data.

Raw Water and Treatment

Aside from desalinators used in some regions of the world that have severe insufficiencies of rain and freshwater and thus must depend upon purified saline waters, drinking water and the water required by industry for a plurality of reasons come from two classes of natural sources. The first is *surface waters* from ponds, streams, rivers, lakes, waterfalls, and glaciers. Natural water precipitation (rain and snow) is the result of Earth's natural hydrologic cycle. Precipitation also reaches below the surface to collect or flow in aquifers and thus is referred to as groundwater. See also **Desalination**.

Prior to the great increases in world population and the development of extensive industrialization and modern agriculture, nature provided a number of built-in processes by which flowing streams essentially can be self-purifying, provided, of course, that pollution of any significant magnitude or intensity did not reach the natural water source. Today, with the exception of very few locales, such pristine conditions do not occur, and, in fact, some form of raw water treatment has existed for nearly five centuries. Traditionally called *waterworks*, or *pumping plants*, the earliest plant is believed to have been one designed by Peter Maurice and located near London Bridge in 1562. Its capacity exceeded 300,000 gallons (1136 cubic meters) for furnishing water to London. The first municipal plant installed in the United States was built in Boston in 1652. Only 15 more plants had been built in the United States by 1800, all located in the northeastern part of the country. The presence of bacteria in public water supplies was the major incentive for treating as well as filtering and pumping water to large municipalities. In terms of the treating operations performed at water treating plants, treating chemicals (including chlorine introduction methods) have grossly improved, and the various processes have increased in size and numbers to handle much greater quantities of water. One of the major factors that distinguishes the water treating plants of the last few decades from their earlier counterparts is the availability of much more sensitive instruments to measure water quality and the automatic control means introduced to accelerate processing reaction time. Public concern and the consequent great expansion of regulatory requirements are the result of raw water supply pollution. Water consumers today also are much more demanding for controlling water taste and odor. Controls over the introduction of toxic wastes (see also **Wastes and Pollution**) have been mandated.

In an average situation, water will be pumped from a natural source, passed through bar screens to remove any large pieces of debris, and moved on to a raw water storage tank for temporary holding. Treating boiler feedwater requires customized methods. See also **Water Treatment (Boiler)**. Raw water treatment plants are found in nearly all municipalities throughout the U.S., Canada, and other advanced countries. Traditionally, these plants have operated under strict regulations and guidelines. Additionally, some industrial firms will re-treat municipal water for a variety of special reasons. Ultrapure water, for example, is required by the semiconductor industry, and means used to obtain ultrapurity include reverse osmosis processes, decarbonators, distillation, deionization, ultraviolet sterilization, and ultrafiltration.

Principal Impurities

Substances that must be removed in order to meet required standards for municipal water fall into three general categories:

1. Suspended matter, color, and organic matter—sediment, turbidity, microorganisms, taste, odor, and other organic matter.
2. Dissolved mineral matter—bicarbonates, sulfate, chlorides of calcium, magnesium, and sodium. Small amounts of silica and alumina commonly are present. Other constituents frequently present

are iron, manganese, fluorides, nitrates, potassium, and sulfuric acid. (The presence of mine drainage components [common in some regions] and components of trade wastes are less frequently encountered today because of severe pollution restrictions. Severely toxic wastes also are controlled, with current regulations in most advanced industrialized nations mandating pretreatment to eliminate or neutralize all such substances prior to disposing of them in public reservoirs. However, municipal water treatment plant managers require the analysis of incoming raw water for the presence of toxic substances.)

3. Dissolved gases—Usually, these are present as oxygen, nitrogen, carbon dioxide, and, less frequently, hydrogen sulfide and methane.

Major Water Treating Operations

The principal operations required to remove and alleviate the undesirable components of raw water include the following.

Sedimentation

With waters containing large amounts of coarse, easily settled, suspended matter, sedimentation (plain sedimentation) is often of value in reducing the load on the filters and effecting economies in amounts of chemicals used for coagulation. Sedimentation may be carried out in sedimentation tanks or basins or in reservoirs. Detention periods vary over a wide range—from a few hours up to one or more months.

Coagulation

Coagulation is employed to form, by cataphoresis and entanglement, larger aggregates with the turbidity, color, microorganisms, and other organic matter present in the water. These larger particles, known as the "floc," may then be removed by filtration through a sand or Anthrafilt filter or by settling and filtration. The coagulant employed is either an aluminum or iron salt, usually the surface. Aluminum sulfate is the most widely used coagulant. Others are ferric sulfate, ferrous sulfate (must be oxidized by air or chlorine) and sodium aluminate. Most favorable pH values for aluminum coagulants usually range from 5.5 to 6.8 and for iron from 3.5 to 5.5 and above 9.0 but there are exceptions. Coagulation aids are ground clay (not too finely pulverized) and activated silica.

Filtration

Filtration is effected by flowing the coagulated or coagulated and settled water downward through a bed of fine filter sand or Anthrafilt is either a pressure type or gravity type filter. Flow rates in industrial practice range up to 3 gpm per sq. ft. (122 liters/min/sq. meter) of filter bed area while in municipal practice maximum flow rate is usually 2 gpm per sq. ft. (81.5 liters/min/sq. meter).

Chlorination

Chlorination is the most widely used disinfecting or sterilizing process. Where daily water requirements are not large, it is common practice to use a hypochlorite, but for large plants liquefied chlorine gas is used. Chlorination may be practiced before filtration (prechlorination), after filtration (postchlorination), or both before and after.

Taste and Odor Removal

Except for sulfur waters, most tastes and odors are organic in nature. Activated carbon is widely used for their removal. In powdered form, it may be added to the water being treated in coagulation and settling equipment. In such installations, aeration is frequently used as preliminary treatment. In granular form, it is used in filters (activated carbon filters or purifiers). As substances producing tastes and odors are usually extremely small in amount, activated carbon filters are frequently operated for 6 months to one or more years before replacement of bed is necessary.

Optional Treating Operations

These may include improving water quality for domestic and industrial purposes.

Hardness Removal (Water Softening)

Sodium Cation Exchanger (Zeolite) Process. This is the most widely used water-softening process in industrial, commercial, institutional and household applications. Hard water is softened by flowing it, usually downward, through a bed (2 feet to over 8 feet in thickness) of a granular or bead type sodium cation exchanger in either a pressure-type (most widely used) or gravity-type water softener. As water comes in contact with sodium cation exchanger, hardness (calcium and magnesium ions) is taken up and held by the exchanger which gives up to the water an equivalent amount of sodium ions. At end of softening run (4 to over 24 hours in industrial practice and 1 to over 2 weeks in household use), softener is cut out of service, regenerated and returned to service (1/2 to 11/2 hours). Regeneration is effected in 3 steps: (1) backwashing to cleanse and hydraulically regrade the bed (2) salting with specified amount of common salt (sodium chloride) solution, usually 10 to 15% in strength, which removes calcium and magnesium from the exchanger and restores sodium to it and (3) rinsing to remove calcium and magnesium chlorides and excess salt.

Hydrogen Cation Exchanger Process. Calcium, magnesium, sodium and other cations are removed by flowing water (usually downward) through a bed (2 feet to over 8 feet in thickness) in an acid-proof pressure-type (most widely used) or gravity-type shell. As water comes in contact with hydrogen cation exchanger, calcium, magnesium, sodium and other cations are taken up by the exchanger which gives up to the water an equivalent amount of hydrogen ions. At the end of operating run (4 to over 24 hours), unit is cut out of service, regenerated and returned to service (11/4 to 2 hours). Regeneration is effected in three steps: (1) backwashing to cleanse and hydraulically regrade the bed; (2) acid treatment with sulfuric or hydrochloric acid which removes metallic cations from the bed and restores hydrogen to it; and (3) rinsing to remove salts (sulfates or chlorides) and excess acid. The carbon dioxide formed from the bicarbonates may be reduced to below 5 to 10 ppm by aeration. The sulfuric and hydrochloric acids formed from chlorides and sulfates may be (1) neutralized with an alkali (usually caustic soda), (2) neutralized by sodium bicarbonate content of a sodium cation exchanger softened water (in which case aeration follows neutralization), or (3) removed by an anion exchanger.

Cold Lime (or Lime Soda) Process. Chemicals used may be (1) lime plus a coagulant or (2) lime plus soda ash plus a coagulant. Dosages vary according to composition of raw water and result desired such as (a) calcium alkalinity reduction, (b) calcium and magnesium alkalinity reduction, (c) reduction of total hardness without excess chemicals and (d) excess chemical treatment. Precipitates produced are calcium carbonate and magnesium hydroxide. Rated residuals without excess chemicals are 35 ppm for calcium and 33 ppm for magnesium, both expressed as calcium carbonate. Operating results will range between these and theoretical solubilities. With excess chemicals, total hardness may be lowered to 16 ppm. The process is best carried out in the sludge blanket-type of equipment in which the treated water is filtered upward through a suspended blanket of previously formed sludge. Detention periods range from one to two hours. Usually, treated water is filtered before going to service but where small amounts of turbidity are unobjectionable, filters may be omitted.

Hot Lime Soda Process. In this process, treatment with lime and soda ash is carried out at temperatures around the boiling point in closed, steel pressure tanks. Heating is usually accomplished with exhaust steam and pressures most widely used range from 5 to 10 psig, but higher pressures up to but seldom above 20 psig are also used. At these temperatures, the reactions proceed swiftly and precipitates formed are larger than those in cold lime soda process so no coagulant is needed. Detention period is one hour and de-aeration effected in primary heater is sufficient to lower dissolved oxygen content to 0.3 milliliter per liter which is sufficient for low-pressure boilers. For high-pressure boilers, either an integral or separate de-aerator is used and this will bring the dissolved oxygen down to less than 0.005 ml/l. With 20 to 30 ppm excess soda ash, the hardness will be reduced to 25 ppm. Softening to practically zero hardness may be effected by either (1) two-stage hot lime soda phosphate treatment in which effluent from hot lime soda softener is treated with sodium phosphate, or (2) the filtered effluent is passed through a sodium cation exchanger. Anthrafilt filters are usually employed with hot process softeners.

Fluoridation

See entry on **Fluorine**.

Demineralization (Deionization)

Metallic cations are removed by a hydrogen cation exchanger. Anions are removed by an anion exchanger. Depending on the hookup used, the carbon

dioxide formed from the bicarbonates may be removed mechanically by an aerator, degasifier or vacuum de-aerator, or chemically by a strongly basic anion exchanger. Strongly basic anion exchangers will remove both strongly ionized acids, such as sulfuric and hydrochloric, and weakly ionized acids, such as silicic and carbonic. Weakly basic anion exchangers will remove only strongly ionized acids.

Iron and Manganese Removal

In clear, deep ground waters, iron and/or manganese may occur as soluble, colorless, divalent bicarbonates. These may be removed (1) by oxidation plus settling (if necessary) plus filtration (2) by cation exchange with sodium or hydrogen cation exchangers or (3) filtration through an oxidizing (manganese zeolite) filter. In (1) addition of an alkali or lime may be needed to build up the pH value so as to speed up the oxidation. Iron and/or manganese in organic (chelated) form may usually be removed by coagulation, settling and filtration. In acid waters, these metals may be removed by neutralization (plus increase of pH), aeration, settling and filtration.

Fluoride Removal

Fluorides may be reduced to below 1 ppm by filtration through a bed of a specially prepared, granular bone char (bone black). Regeneration is effected with caustic soda solution followed by treatment with dilute phosphoric acid.

Dissolved Gases

Oxygen and Nitrogen may be removed (1) hot in a deaerating heater (de-aerator) or (2) cold in a vacuum de-aerator. *Carbon dioxide* may be removed in (1) an aerator, (2) a de-aerating heater or (3) a vacuum de-aerator or it may be neutralized with lime or an alkali or by filtration through a bed of granular calcite. *Hydrogen sulfide* may be removed by (1) aeration followed by chlorination, (2) treatment with flue gas plus aeration followed by chlorination or (3) filtration through an oxidizing manganese zeolite filter (household use). If sulfur content and pH values are high, (1) may effect but little removal but, in some cases, with fairly long detention periods, sulfur bacteria may effect notable reductions.

Treatment of Wastewater (Sewage)

Wastewater may be defined as the spent or used water from a community or industry that contains dissolved or suspended matter. Toxic wastes must receive pretreatment by the polluter prior to introduction into a water reservoir or municipal used-water return lines. Most wastewater is 99.94% water by weight. The remaining 0.06% is material dissolved or suspended in the water. Water chemists differentiate *suspended solids* and *dissolved contaminants*. The concentration of dissolved or suspended matter usually is expressed as milligrams of pollutants per liter of water (mg/l), or as parts per million (ppm) (weight). On another scale, 1 ppm can be visualized as being equivalent to 1 minute of time in 1.9 years. Although pollutants may be so minute, innumerable studies have shown their adverse effects on human and other animal life.

A generally accepted estimate is that each individual, on a national (U.S.) average, contributes approximately 265 to 568 litres of water per day to a community's wastewater flow. While most people think of wastewater as only "sewage," wastewater also comes from other sources—commercial, industrial, and storm and ground water. Generally, each house or business has a pipe or sewer that carries the wastewater to the wastewater treatment plant. **Sanitary sewers** carry only domestic and industrial wastewater, while **combined sewers** carry wastewater and storm water runoff. Every reasonable effort is made to exclude storm (inflow) and ground (infiltration) water from the sanitary sewer system. These efforts are usually less successful on older sewer systems that leak.

The wastewater from the sewer system either flows by gravity or is pumped into the treatment plant. Usually, treatment consists of two major steps, primary and secondary, along with a process to dispose of solids removed during the two steps.

In **primary treatment**, the objective is to physically remove suspended solids from the wastewater, either by screening, settling, or floating. The major goal of **secondary treatment** is to biologically remove contaminants that are dissolved in wastewater. In secondary treatment, air is supplied to encourage the natural processes of growth of bacteria and other biological organisms to consume most of the waste. These organisms and other solids are then separated from the wastewater. Before discharge to the **receiving stream**, the water usually passes through a tank where a small amount of chemical (usually chlorine) is added to disinfect the treated water.

In primary and secondary treatment, solids are settled and removed for further processing. Solids, usually referred to as sludge, are normally processed in three steps—digestion, dewatering, and disposal. The digestion step reduces the volatile solids and prepares the sludge for further processing. Dewatering involves the application of a variety of processes that reduces the water content of the sludge and, in turn, its volume. The final step is the ultimate management of this treated material, or biosolids, which can be used beneficially through methods such as land application. See Figs. 6 and 7.

Screening removes large floating objects from the incoming wastewater stream. Treatment plant screens are sturdily built to withstand the flow of untreated wastewater for years at a time. Rags, wood, plastics, and other floating objects could clog pipes and disable treatment plant pumps if not removed at this point. Typically, screens are made of steel or iron bars set in parallel about one-half inch apart. Some treatment plants use a device known as a comminuter, which combines the functions of a screen with that of a grinder.

Sand, grit, and gravel flow through the screens to be picked up in the next stage of primary treatment—the grit chamber. Grit chambers are large tanks designed to slow the wastewater down just long enough for the grit to drop to the bottom. Grit is usually washed after its removal from the chamber and buried in a landfill.

After the flow passes out of the grit chamber, it enters a more sophisticated settling basin called a sedimentation tank. Sedimentation removes the solids that are too light to fall out in the grit chamber. Sedimentation tanks are designed to hold wastewater for several hours. During that time the suspended solids drift to the bottom of the tank, where they can be pushed into a large mass by mechanical scrapers and pumped out of the bottom of the tank. The solids removed at this point are called primary sludge. The primary sludge is usually pumped to a sludge digester for further treatment. During the sedimentation process, floatable substances, such as grease and oil, rise to the surface and are

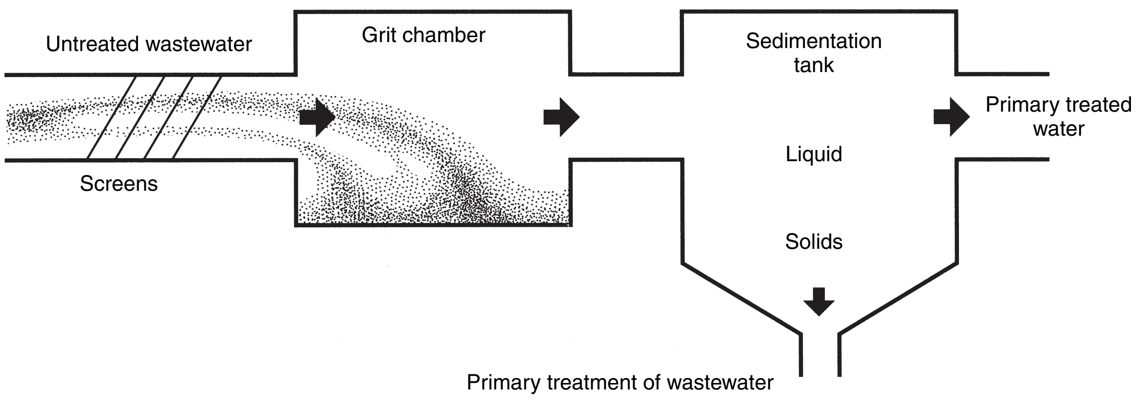

Fig. 6. Wastewater entering a treatment plant receives primary treatment first. In this state, a series of operations removes most of the solids that can be screened out, will float, or will settle

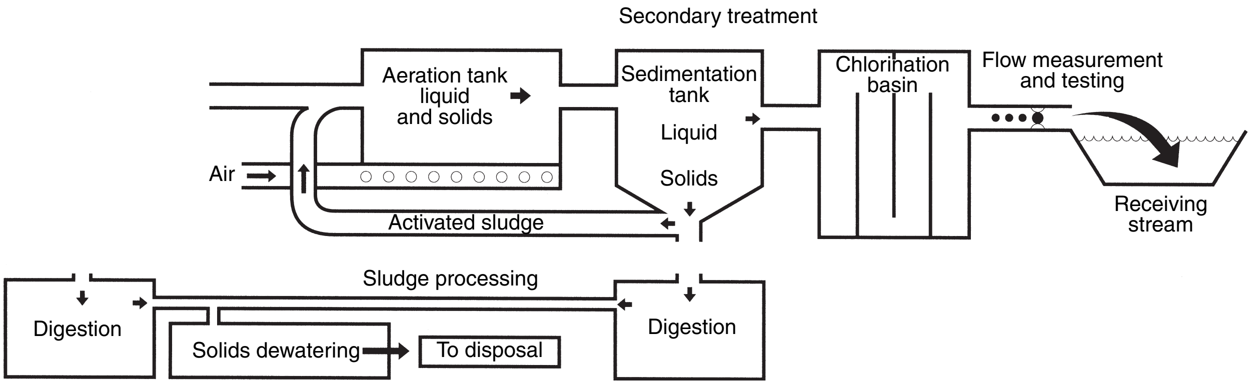

Fig. 7. Wastewater flowing out of primary treatment still contains some suspended solids and other solids that are dissolved in the water. In a natural stream, such substances are a source of food for protozoa, fungi, algae, and hundreds of varieties of bacteria. The secondary treatment stage is a highly controlled artificial environment in which these same microscopic organisms are allowed to work as fast and efficiently as they can. The microorganisms biologically convert the dissolved solids in the wastewater to suspended solids that will physically settle out at the end of secondary treatment

removed by a surface skimming system. The skimmed materials are either sent to the sludge digester for treatment along with the primary sludge or are incinerated. Sedimentation marks the end of primary treatment. At this point, most of the solids in the stream that can be removed by the purely physical processes of screening, skimming, and settling have been collected. An additional set of techniques using biological processes must be employed next. (*After Water Environment Federation.*)

There are several different ways to optimize biological conversion. Secondary treatment promotes the growth of millions of microorganisms, bringing them into close contact with the wastewater on which they feed. Care is taken to make sure that the temperature, oxygen level, and contact time support rapid and complete consumption of the dissolved wastes. The final products are carbon dioxide, water and more microorganisms. Three widely employed types of secondary treatment are common: activated sludge, trickling filters, and lagoons.

The most common is the activated sludge process. Activated sludge processes are much more tightly controlled than either trickling filters or lagoons. In this form of treatment, wastewater and microorganisms are mixed for a few hours in a large tank by constant aeration and agitation. Once the aeration is complete, the mixture of water and microorganisms flows to a sedimentation tank similar to the one used in primary treatment. The microorganisms and other solids settle to the bottom of the sedimentation tank. Since activated sludge is a continuous process, a portion of the settled solids (return activated sludge) are circulated back to the beginning of the process to serve as “seed” organisms. The part not needed for “seed” is commonly called waste activated sludge and is sent to a sludge digester for further treatment. (*After Water Environment Federation.*)

Sludge Handling

Treatment professionals refer to solids in general as **sludge**. Beneficial sludges are called “biosolids.” But these solutions are not the thick, molasses-like substances that most people think of when they hear the word “sludge.” Wastewater sludges are slurries of water and solids that are roughly 100 times more concentrated than untreated wastewater. That is, they contain about 3% solids compared to the. 03% (or less) concentration of the initial flow into a treatment plant. The various techniques for handling these flows are designed to increase the solids concentration even further, to as much as 50%.

As a rule of thumb, higher degrees of wastewater treatment produce larger volumes of sludge. For example, primary treatment usually produces 2500 to 3500 gallons of sludge for every 1 million gallons of wastewater. Secondary treatment usually produces 15,000 to 25,000 gallons for every 1 million gallons treated. To try to dispose of or recycle such volumes of waste is practical. Thus, sludge handling methods are designed to remove as much water from the mixture as possible.

The spectrum of sludge handling techniques is divided into processes that condition, thicken, stabilize, and dewater the sludge flow. Conditioning operations usually employ chemicals or heat to make the sludge release water more easily. Thickening techniques use gravity, flotation, and chemicals to separate water from the solids. Conditioning and thickening are usually the first steps in handling primary and secondary sludges.

Stabilization converts the organic matter in the sludge so that the biosolids can be disposed of or used as a soil conditioner without posing a health hazard in the general environment. Sludge stabilization can occur with (**aerobic**) or without (*anaerobic*) oxygen in special tanks called digesters. Sometimes chemicals such as lime are used for stabilization.

Dewatering is done by mechanical means. Filters, centrifuges, and presses remove even more water from the biosolids. Biosolids dewatered by such equipment have the consistency of wet mud and can have a solids concentration of up to 20%. Other techniques, such as drying beds or special presses, can be used to dewater the sludge, producing up to 50% solids—about the consistency of dry soil. At the end of a sludge handling process, the concentrated solids can be placed in landfills, incinerated, applied to land, or composted for use as a soil conditioner.

Alternatives to Sludge Process

For some wastewater treating situations, the complexities of the sludge process may not be required. In such instances, trickling filters or lagoons may be used.

Trickling filters

are large beds of coarse, loosely packed material—rocks, wooden slats, or shaped plastic pieces—over which the wastewater is sprayed or spread. The surfaces of the filter material (also known as the “medium”) become breeding grounds for the microorganisms that consume the wastes. A common trickling filter is a bed of stones 3 to 10 feet deep. Under the bed, a system of drains collects the treated wastewater and diverts it to a sedimentation tank or back over the filter medium for additional treatment. In the sedimentation tank, suspended solids settle and are pumped to a sludge digester. Trickling filters are relatively simple to construct and operate. Many communities in the United States rely on them for secondary treatment.

Lagoons are used by some communities to achieve secondary treatment. Lagoons generally treat the total wastewater from a community until the biological oxidation processes have consumed and converted most of the wastes present. This form of treatment depends heavily on the interaction of sunlight, algae, and oxygen. Sometimes the wastewater is aerated to speed the process, since these interactions are relatively slow. There is usually no sedimentation tank associated with a lagoon. Suspended solids settle to the bottom of the lagoon, where they remain or are removed every few years. Generally speaking, lagoons are simpler to operate than other forms of secondary treatment, but are less efficient.

At the end of a secondary treatment process, the wastewater is disinfected to remove disease-causing organisms. Usually, an agent such as chlorine is added to the stream of wastewater before it is discharged to receiving waters. Sometimes other techniques are used if the receiving waters are sensitive to the addition of chlorine.

An alternate to secondary and higher levels of treatment is land application of wastewater. The wastewater is usually sprayed over natural or specially sloped and seeded land. The wastewater seeps into the soil where natural solid microorganisms consume the wastes. The treated water is either used by plants, stays in the ground, or is collected and routed to a receiving stream.

Role of Sunlight as a Detoxifying Agent

In the late 1980s, Sandia National Laboratories announced the development of a solar-powered reactor to generate low-cost electrical power and recently have found an alternative use for it, namely, for the detoxification of polluted water. As stated by the project leader, C. Tyner, "We believe this process will destroy most organic materials, including industrial solvents, pesticides, dioxins, PCBs, and munitions chemicals." The process breaks down toxic chemicals into smaller, safer molecules. Current methods remove organic wastes from water by bubbling air through the water and thus volatilizing them for release into the atmosphere (not attractive) or by running the polluted water through carbon filters. The researchers have set up a troughlike arrangement (similar to sunlight collectors used for solar furnaces) along which runs a radiation-transparent tube holding the flowing water, which thus receives a maximum concentration of solar radiation. The future of the project will be determined largely by cost considerations.

WATER (Hard). Water containing low percentages of calcium and magnesium carbonates, bicarbonates, sulfates, or chlorides as a result of long contact with rocky substrates and soils. Degree of hardness is expressed either as grins per gallon or parts per million (ppm) of calcium carbonate (1 grain of $CaCO_3$ per gal is equivalent to 17.1 ppm). Up to 5 grains is considered soft, more than 30 grains very hard. Hardness may be temporary (carbonates and bicarbonates) or permanent (sulfates, chlorides). Treatment with zeolites is necessary to soften permanently hard water. Temporary hardness can be reduced by boiling. These impurities are responsible for boiler scale and corrosion of metals on long contact. Hard waters require use of synthetic detergents for satisfactory sudsing.

Water Pollution in the United States[1]

For an abridged analysis of the water pollution problem in the United States, a concerted look is taken at (1) the rivers and (2) groundwater.

Water Quality in the Rivers. River water serves as an excellent overall index of the pollution problem, because ultimately, most water, even consumed groundwater and a vast majority of the lakes, ponds, etc., in the long run ends up in a river (or series of rivers), and thence flows to the oceans. The majority of rivers are accessible with relative ease and thus add to the convenience of obtaining water samples for analysis.

Probably the most complete study of river water quality was completed by the U.S. Geological Survey, released in early 1987 and periodically updated. The initial survey was coordinated by Smith and Alexander (USGS) and Wolman (The Johns Hopkins University), including water quality records from two nationwide sampling networks. The network included over 300 locations on the major rivers of the United States. Twenty-four water quality parameters are measured. Originally, the two networks were comprised of: (1) the National Stream Quality Accounting Network (NASQUAN) and (2) the National Water Quality Surveillance System (NWQSS). Locations of stations are shown on the map in Fig. 1. The measured water-quality indicators include:

pH (hydrogen ion concentration)	Trace Elements
Alkalinity ($CaCO_3$)	Arsenic
Sulfate (SO_4)	Cadmium
Nitrate (total as N) (TN)	Chromium
Phosphorus (total as P) (TP)	Lead
Calcium	Iron
Magnesium	Manganese
Sodium	Mercury
Potassium	Selenium
Chloride	Zinc
Suspended sediment (SS)	
Fecal coliform bacteria	
Fecal Streptococcal bacteria	
Dissolved oxygen	
Dissolved-oxygen deficit (DOD)	

(1) The National Stream Quality Accounting Network (NASQAN), indicated by solid black dots in map; and (2) the National Water Quality Surveillance System (NWQSS), indicated by open black circles on map. Shown in outline are regional drainage basins. Abbreviations used for these basins are:

[1] It is interesting to note how interrelated the topics of water, air, and solids (soil) pollution are. Acid rain, for example, commences as an air pollutant and ends up as a soil and water pollutant. See also **Pollution (Air)**. Thus, water pollution may be direct or indirect. Because they have a mass, air pollutants ultimately fall to Earth's surface and thus pollute the oceans, bodies of freshwater, and the land.

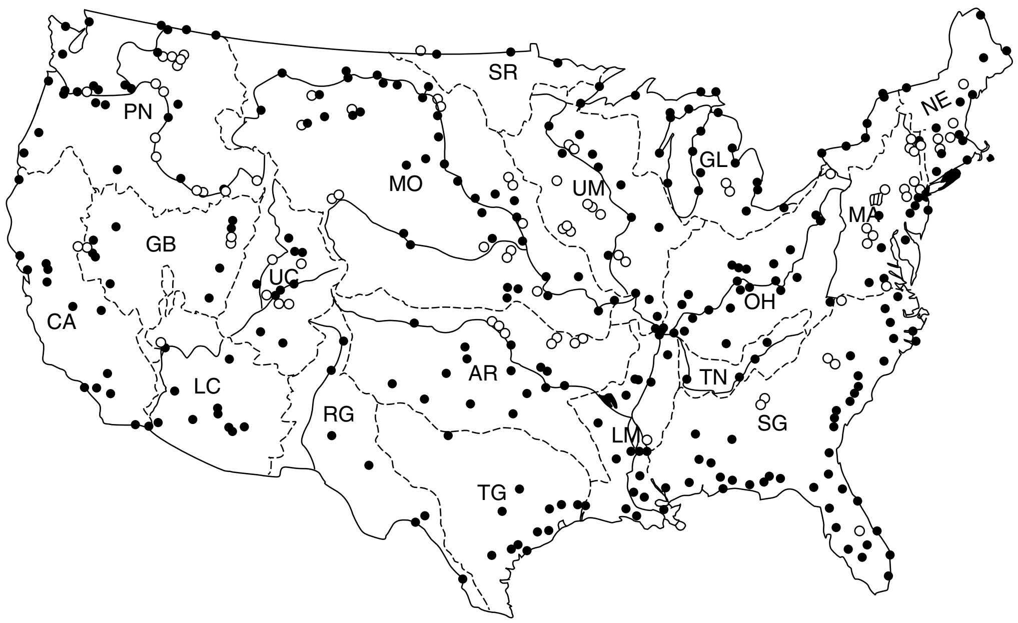

Fig. 1. Analysis of major river waters based upon a sampling network comprised of over 300 stations and involving two systems

NE New England	UM Upper Mississippi	RG Rio Grande
MA Mid-Atlantic	LM Lower Mississippi	LC Lower Colorado
SG Southeast-Gulf	TG Texas-Gulf	UC Upper Colorado
TN Tennessee	AR Arkansas-Red	GB Great Basin
OH Ohio	MO Missouri	CA California
GL Great Lakes	SR Souris-Red-Rainy	PN Pacific Northwest

The largest rivers are shown as solid black lines. The NASQAN stations are located and associated with these rivers and their tributaries; the NWQSS stations are located along smaller rivers and usually near agricultural areas and some urban communities. (*U.S. Geological Survey.*)

Particularly noteworthy are widespread decreases in fecal bacteria and lead concentrations and widespread increases in nitrate, chloride, arsenic, and cadmium concentrations. Recorded increases in municipal waste treatment, use of salt on highways, and nitrogen fertilizer application, along with decreases in leaded gasoline consumption and regionally variable trends in coal production and combustion during the period, appear to be reflected in water-quality changes. In addition to data from the network of sampling stations, the researchers depended upon considerable ancillary data in their interpretation of the sampling station trend results.

Because of the passage of restrictive legislation, mainly over the past decade, improvements in river water quality can and should be expected. As discussed later, indirect pollution of landfills as they reach underground aquifers is an even more important concern and is less visible and hence less easy to police and control.

Since the passage of the Clean Water Act by the U.S. Congress, numerous improvements have been evidenced and thus tend to reinforce confidence that in many aspects the environment can be improved.

Trends in River Water Pollution

Biological Oxygen Demand (BOD). The Clean Water Act was passed by the U.S. Congress in 1972. In the decade that followed, municipal loads of BOD decreased an estimated 46% and industrial BOD loads decreased at least 71% nationwide. These reductions are impressive, especially in light of an increase in population (up 11% during the period) and an increase in the gross national product (GNP, adjusted for inflation) of 25%. Federal funding for upgrading municipal facilities peaked in 1980 and amounted to $35 billion for the decade.

Dissolved Oxygen Deficit (DOD). The sampling station report indicated a net decrease in DOD (thus an improvement in dissolved oxygen conditions). DOD declines were reported in the New England, Mid-Atlantic, Ohio, and Mississippi regional basins; increases were most frequently found in the Southeast. These data appear to confirm the success of point-source control efforts. Decreases in DOD were found most often (beyond expectations) where point sources dominated; increases where nonpoint sources prevailed. The chronology of the station data also indicates that gains from industrial water treatment preceded those from modernization of municipal facilities.

Fecal Bacteria (coliform, FC; streptococcal, FS). During the study period, decreases in FC and FS were widespread. Major decreases were particularly evident in parts of the Gulf Coast, central Mississippi, and Columbia basins; significant decreases were also noted in the Arkansas-Red basin and along the Atlantic Ocean. During the study period, major efforts were made to control both municipal and agricultural sources of fecal bacteria.

Suspended Sediment (SS). These impurities, originating from nonpoint sources (notably agricultural) are probably the most damaging nonpoint sources of water pollution. E.H. Clark estimates the cost of the hydrologic impacts of soil erosion and related nutrients on aquatic ecosystems may increase. Fertilizer application rates increased by 68% during most of the testing period described here. The long-term history of fertilizer in the United States has been one of almost continuous increases in nitrogen and phosphorus application rates. As reported by Smith, et al., the extent to which changes in agricultural practice are reflected in trends of SS, phosphorus, and nitrogen concentrations in the nation's rivers has largely been a matter of conjecture because of the lack of systematic long-term studies.

Certain forms of land use, such as logging, traditionally have been associated with high rates of soil erosion. Thus, the study indicated large increases in SS in the Columbia (logging) and in the Arkansas-Red and Mississippi basins (agriculture) during the test period. Significant amounts of SS were also found along the Texas Gulf Coast, northern Florida, and scattered locations in northern Ohio, New England, and northern Minnesota. Declining rates of SS were indicated in the Missouri River basin and have been clearly traced to the effects of reservoir construction throughout that basin during the 1950s and 1960s.

Total Phosphorus (TP). Mainly as the result of controls over point sources of pollution, decreasing trends in TP were found in the Great Lakes and Upper Mississippi regions. Significant correlations in TP increases were found in connection with nonpoint sources (mainly agriculture) in several regions.

Total Nitrate (TN). Increases in TN were found to be widespread. Although also found to be significant in the Pacific Northwest and along the California coast, the great majority of increases in TN were found east of the 100th meridian (southward from North Dakota to southern Texas). Increases of TN were strongly associated with agricultural activity including fertilized acreage (as a percentage of basin area), livestock population density, and feedlot activity. Atmospheric deposition, in addition to agricultural runoff, was found to be a major source of nitrate in surface waters, East and northern Midwest. Separate studies of NOx

emissions showed a general pattern of increasing rates, notably in the Ohio, Mid-Atlantic, Great Lakes, and Upper Mississippi basins. The river water quality study correlated well with the emission studies.

It is interesting to note that the differences in nitrogen and phosphorus trend patterns appear to be the result of three factors: (1) atmospheric deposition seems to play a large role in the high frequency of nitrate trends; (2) the low frequency of, and strong association patterns between phosphorus and SS trends suggests that increases in TP resulting from rises in agricultural activity have been moderated or delayed by temporary storage of sediment-ground TP in stream channels; and (3) during the study, point-source control efforts were focused much more intensely on TP than on TN because phosphorus was considered more limiting to eutrophication in freshwater ecosystems. The greatest consequence of the differences in TN and TP were seen in changes in the delivery of nutrients to coastal areas. Nitrate loads to East Coast estuaries, the Great Lakes, and the Gulf of Mexico have increased markedly, while phosphorus loads to coastal areas have changed little or have declined. Exceptions are the Gulf Coast and the Pacific Northwest basins, in which instances phosphorus loads to estuaries have increased in association with substantial increases in sediment loads. Researchers have stressed that increased delivery of nitrate to estuaries is of major concern because of the tendency for nitrogen to be limiting to eutrophication in many estuarine environments. See Table 1.

Salinity. Increasing trends in chloride, sulfate, and sodium were found in a large majority of the rivers tested. An average increase of 30% in salinity was found. Researchers attribute this increase to the following factors. (1) Increases in population in the basins surveyed—human wastes are a major source of chloride in populated basins. (2) Use of salt on highways increased by a factor of 12 between 1950 and 1980 and is considered a major contributor to total stream salinity. (The rates of highway salt use were particularly significant in the Ohio, Tennessee, lower Missouri, and Arkansas-Red basins.) (3) In the Missouri, Arkansas, and Tennessee basins, salinity increases were accurately correlated with changes in surface coal production during the testing period. By contrast, salinity decreased in the Upper Colorado Basin, an area historically plagued with salt problems. Decreases are attributed to control efforts and the effects of reservoir filling during the early 1970s.

Trace Elements. Moore and Ramamoorthy reported that trends in toxic element concentrations in surface waters have remained largely unknown despite rapidly increasing knowledge of the potential sources of toxic substances in aquatic systems. The study reported on analyses of several trace elements, including arsenic, cadmium, chromium, lead, iron, manganese, mercury, selenium, and zinc. Researchers found increases in dissolved arsenic and cadmium, particularly in those basins in the industrial Midwest. Atmospheric deposition is considered more significant than terrestrial sources of trace element contamination. Heit et al. confirmed this conclusion as based upon the results of lake sediment analyses in regions with high deposition of fossil-fuel combustion products. At many network sampling stations, dissolved lead concentrations showed a decrease, but despite significant declines in gasoline lead consumption, some sampling stations showed no decline. Lead concentrations were found particularly heavy in the Texas Gulf Coast region.

In deference to the excellence of the sampling study, researchers point out that additional sampling in selected smaller basins is needed to improve the ability to determine the effects of changes in point-source pollution.

TABLE 1. CHANGES AND TREND PATTERNS OF DELIVERY OF NUTRIENTS TO COASTAL AREAS OF THE UNITED STATES

	Change in load	
Region	Nitrate (%) total	Phosphorus (%) total
Northeast Atlantic Coast	32	−20
Long Island Sound/New York Bight	26	−1
Chesapeake Bay	29	−0.5
Southeast Atlantic Coast	20	12
Albemarle/Pamlico Sound	28	0
Gulf Coast	46	55
Great Lakes	36	−7
Pacific Northwest	6	34
California	−5	−5

Source: Smith/Alexander/Wolman 1987 reference listed.

Although the effects of improved sewage treatment on dissolved oxygen levels appear to be more localized than previously thought, it is possible that the ecological and social benefits of water-quality improvements have been large in proportion to their spatial extent. As pointed out by W.M. Leo, et al., individual case studies have demonstrated local effects of point-source pollution controls, but they do not provide an adequate national sample on which to base an assessment of the benefit of pollution abatement programs. Smith/Alexander/Wolman, in their report, suggest that in designing water-quality monitoring programs for the future, we should recognize the growing number of both point- and nonpoint-source issues that our economic and political systems must address.

Groundwater Quality and Contamination

Groundwater as used by humans consists of subsurface water, which occurs in fully saturated soils and geological formations. Nearly half the population of the United States uses groundwater from wells or springs as a primary source of drinking water. An estimated 75% of major cities depend upon groundwater for most of their supply. Total fresh groundwater withdrawals (1980) were estimated at 88.5 billion gallons per day, of which 65% was used for agricultural irrigation. Numerous regulatory acts have been passed by the U.S. Congress in recent years to protect groundwater from pollution. These various acts are listed in article on **Wastes and Pollution**.

As early as the 1980s, the U.S. Environmental Protection Agency (EPA) proposed a national groundwater strategy—with the emphasis of targeting on prevention as contrasted with taking remedial action in treating known contaminated sites. Transport of groundwater is very slow. Flow rates are governed by hydraulic gradients and aquifer permeability, thus flows may range from a few centimeters to a meter or so per day. Contaminants usually mix with the water at a low rate. Sometimes natural ingredients tend to retard the actions of contaminants; in other cases the concentrations of contaminants in groundwater may exceed those found in surface water. Groundwater contamination occurs out of view and the effects of pollution may not be noted for weeks or months (even years in sparsely settled communities) after the initial cause(s). A wide variety of substances are involved in groundwater contamination. These include inorganic ions (chloride, nitrate, heavy metals), complex synthetic organic chemicals, and pathogens (viruses and bacteria). Thus, rarely does one find the same combination of variables when attacking a groundwater contamination problem.

The extent of groundwater is statistically very impressive: (1) of the water in the hydrologic cycle, 4% is groundwater, exceeded only by the seas and oceans; (2) groundwater volume at any given time exceeds that of the combined fresh water in lakes, streams, and rivers, of which an estimated 30% of the volume is furnished by groundwater; (3) during dry spells, groundwater furnishes a large majority of the low water flow of streams.

The manner in which waste disposal practices may interact with and contaminate the groundwater system is illustrated schematically in Fig. 2.

A study of groundwater contamination in ten selected states, sponsored by the Environmental Assessment Council of the Academy of Natural Sciences (Philadelphia) provides an excellent view of the sources and kinds of contamination that have been found in known, reported incidents of contamination. See Table 2.

One of the most serious cases of groundwater pollution occurred above the Great Miami Aquifier, which is a 2-mile (3.2-km) wide and 80-mile (129-km) long water basin that essentially follows the Great Miami River in southern Ohio and a section of which is located directly under the city of Hamilton. This aquifer is considered to be one of the Midwest's most productive sources of groundwater, making up about one-third of Ohio's groundwater. At points, the aquifer rises to within 20 feet (6 m) of ground level. A small, private firm established a waste-disposal operation in the 1970s at a time when regulations were minimal. Cleaning up the severely polluting operation commenced in May 1983 and was one of the first projects selected by the EPA to clean up after passage of the Superfund Act in late 1980. Cleanup contractors found 8600 drums, 30 storage tanks, and two open-top tanks on an approximately 10-acre (40,470–square-meter) area. Containers were found holding and leaking some 300,000 gallons (1,135,000 liters) of toxic wastes, including pesticides, rodenticides, waste oils, plastics and resins, acids, arsenic, and cyanide sludges. Among the chemicals found were DDT and PCBs. It was estimated in 1990 that environmental correction actions will require an additional 10 years at a multimillion dollar cost. Professionals in the cleanup field have estimated

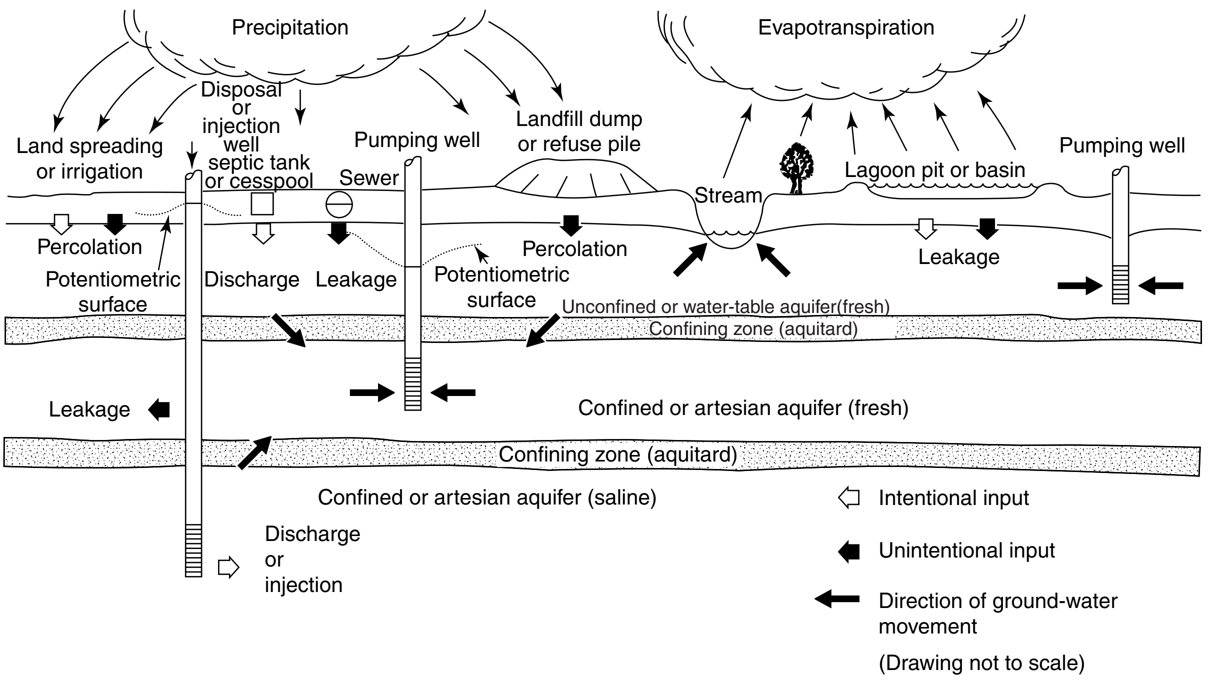

Fig. 2. Processes by which wastes can reach and contaminate groundwater systems. (*U.S. Environmental Protection Agency*)

TABLE 2. REPORTED INCIDENTS OF GROUNDWATER CONTAMINATION IN TEN SELECTED STATES (ACADEMY OF NATURAL SCIENCES, PHILADELPHIA)

State	Groundwater consumed (million gallons/day)	Source of contamination
Arizona	4800	Industrial wastes; landfill leachate; human and animal wastes
California	13,400–19,000	Saltwater intrusion; nitrates from agriculture; brines and other industrial and military wastes
Connecticut	116	Industrial wastes, petroleum products, human and animal wastes
Florida	3000	Chlorides from saltwater intrusion and agricultural return flow; industrial wastes; human and animal wastes
Idaho	5600	Human and animal wastes; industrial wastes; radioactive wastes
Illinois	1000	Human and animal wastes; landfill leachate; industrial wastes
Nebraska	5900	Irrigation and agriculture; human and animal wastes; industrial wastes
New Jersey	790	Industrial wastes; petroleum products; human and animal wastes
New Mexico	1500	Oil field brines; human and animal wastes; mine wastes
South Carolina	200	Petroleum products; industrial wastes; human and animal wastes

Note: Probably the most newsworthy, publicized incidents have stemmed from public and industrial dumping sites, covered in this summary under "landfill leachate." A class of pesticides most commonly found in groundwater is nematocides. They are particularly difficult because manufacturers design them to be both persistent and toxic. DBCP (1,2-dibromo-3-chloropropane) is a representative nematocide.

the existence of about 400 additional sites of serious groundwater pollution of the extent and nature of the site just described.

Remediation of Poisoned Aquifers. Means for correcting polluted underground water systems are limited and costly. To the knowledgeable would-be polluter, the costs and time involved serve as incentives for preventing such damage in the first place.

Containment. Once subterranean pollution has been detected for the first time, not only must the source(s) be located, but the extent of damage must be determined. This often involves the meticulous analysis of core samples and thorough geologic and hydrologic mapping of the poisoned volume of earth and groundwater affected. Effective permanent remedial actions require an extensive and reliable data base. In some cases it may be found that, by way of constructing underground barriers, the polluted underground sections can be isolated and an aquifer rerouted. In such rerouting, it may be found that gravity flow underground may be insufficient, thus requiring pumps to assure flow through what, in essence, is a new "artery" for groundwater flow.

Where containment (isolation) procedures are not practical or fully adequate, extraction of pollutants may be required.

Extraction. In this process, sometimes referred to as the "pump and treat" method, polluted water is pumped to the surface, after which it is treated to remove toxic materials. Then the treated water is returned to the aquifer. Depending upon the extent of pollution, a large water-treating facility may be required adjacent the cleanup site, even though the facility may be required only for a comparatively short time of a few to several months.

Bioremediation. This process is gaining acceptance among site cleanup professionals. Wastes that have been pumped out of the aquifer are transferred to specially constructed tanks, to which fungi, bacteria, and other microbes are added, along with hydrogen peroxide, which furnishes oxygen. Also added are small amounts of nitrogen fertilizer, which acts as a nutrient for the microbes. Under these ideal conditions, the microorganisms secrete enzymes that transform immense quantities of substances such as benzene and trichloroethylene into harmless salts. A delicate balance must be maintained in providing just enough oxygen and nutrients, thus avoiding repollution of the wastes.

For cleaning up sites less extensive than the one just described, and thus requiring aboveground treating facilities for less time, portable plants are receiving consideration. New techniques also are being evaluated. In one system, a *wet oxidation* process converts waste sludge into clean water and sterile ash. Organic pollutants also are being subjected to a laser oxidation process that breaks molecular bonds in a photochemical reaction chamber. Low-frequency soundwaves and electric charges also are being tested to free pollutants from soils. In this process, after a positively charged anode is introduced to the ground, positively charged water and contaminants migrate toward a negatively charged withdrawal well, which acts as a cathode.

Above- and Underground Storage of Products and Wastes

For practical economic reasons, some potentially polluting products must be stored for indeterminate periods above ground. Chemical, petroleum, and petrochemicals are examples of the need for temporary holding. In the blending of gasolines, for example, refineries pump different grades

of fuel to a "gasoline pool," out of which quantities can be drawn and blended to achieve the desired specifications for a given gasoline. In producing commercial chemicals where batch or semibatch processing is used, a supply for several weeks or months may be produced within a short time frame and then stored in inventory to fill orders over a period much longer than that required to make the product. Thus, numerous products that are considered toxic must be inventoried. Frequently, at the manufacturing level, aboveground tanks are preferred. In terms of gasoline, at the consuming level, safety regulations and sheer convenience require that fuels be dispensed from underground tanks. Unfortunately, over the years, tank leaks have become an important cause of land pollution and ultimately the poisoning of aquifers.

Other toxic products that require some form of storage include solvents, chemical raw materials (fluid) and wastes that are "waiting" for final disposal/destruction.

Pollutant Pathways When Leaked Follow Different Pathways Underground. Relatively recently, cleanup specialists have made the surprising discovery that organic substances generally differ from inorganic substances when they are leaked underground. See Fig. 3. This information is helpful for preventing future leaks and for remedying situations where pollution already has occurred.

Means for Preventing Tank Leakage. In addition to the "common sense" approaches, such as selecting corrosion, weather, and moisture-resistant materials of construction, providing excellent foundations, and leak-detection instrumentation, there are additional preventive measures that can be taken. Cathodic protection, for example, is described in an article on **Corrosion**.

Secondary containment of underground storage tanks is another means. EPA regulations now require secondary containment systems for hazardous substance underground storage. Many industrial firms now are turning to flexible membrane systems, which offer a number of advantages over their rigid counterparts. EPA regulations for new tank construction permit four options:

1. Fiberglass-reinforced plastic.
2. Steel with cathodic protection, using either dielectric coating, field installation by a corrosion expert, or impressed current system.
3. Metal without cathodic protection if site is determined to be noncorrosive.
4. Steel-fiberglass–reinforced plastic composite.

Options for existing tanks include:

1. Interior lining.
2. Cathodic protection if internal inspection is conducted and tank is less than 10 years old and is monitored monthly.

Landvaults. Approval of aboveground permanent landvaults sometimes can be obtained. They have a number of advantages:

1. A double or triple composite liner system provides maximum protection.
2. They permit future retrieval of wastes for improved treatment when such a process may be developed, and, inasmuch as the vault is fully sealed, the underground geology need only be strong, stable, and free of any tectonic history.

Pollution of the Seas and Oceans

Over the centuries, populations living along the tens of thousands of miles of coastline of the oceans and seas worldwide have dumped their refuse into these sinks of saline water. This was done with little if any reluctance or concern prior to the early 1900s. Ocean waters, without desalination, could not serve as drinking or irrigation water, and, inasmuch as these bodies of water are so tremendous as compared with the amounts of waste that may be added to them, there was no real sense of guilt when polluting them. Only within the last few decades has a public awareness of pollution of all types, including the oceans, developed. Modern means for exploring Earth's hydrosphere, from the surface to great depths, are relatively recent achievements. The American explorer, Charles Beebe, did not accomplish his remarkable descent to ocean depths until 1934, when he reached a depth of 3028 feet (923 m).

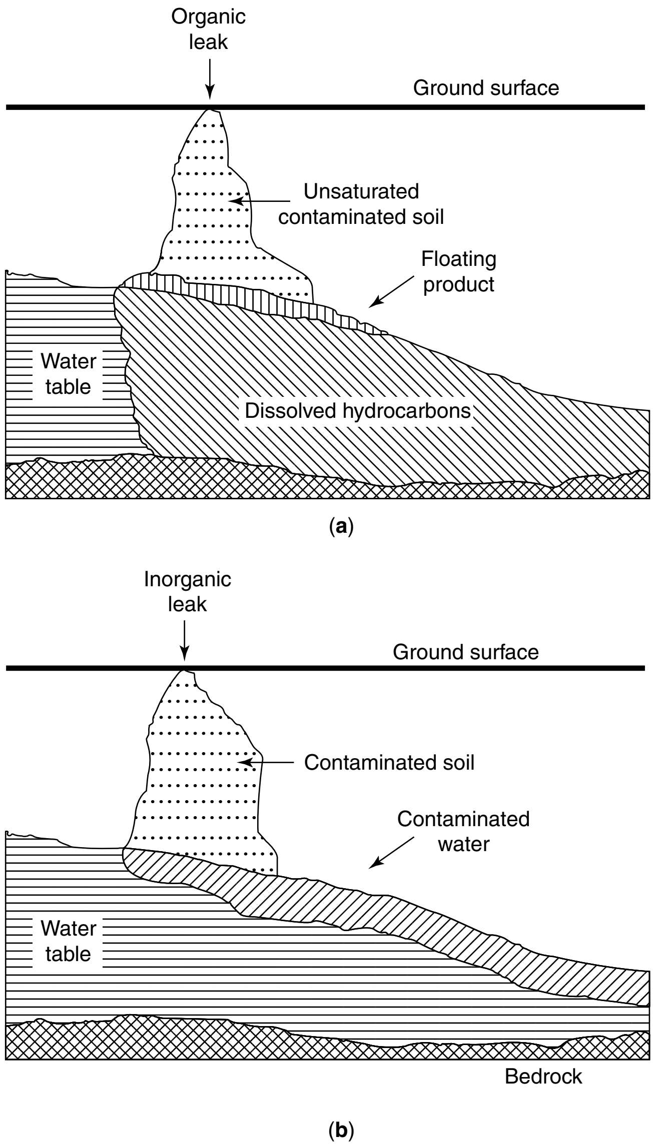

Fig. 3. Schematic diagrams illustrate how organic and inorganic fluids differ in how they permeate ground and water table: (**a**) Organic substances contaminate the soil to the surface of the groundwater table. If contaminant is lighter than water and only slightly soluble, such as a petroleum product, a substantial layer of product may be found floating on the groundwater surface. The groundwater will contain varying concentrations of dissolved contaminants, depending upon solubility. (**b**) Inorganic compounds, such as acidic wastes containing metals, may be attenuated in their flow. Soils tend to attenuate movement of positively charged ions (cationic) metals at various rates, depending on the cation exchange capacity of the soil. Clays have a high cation exchange capacity. Thus, extensive contamination of soils by metals is infrequent. In contrast, acids can increase movement through the soil

The effects of polluted waters on the proliferation and edibility of fishes and other forms of ocean life have been researched extensively in recent years, and this knowledge has created a vital incentive for reducing pollution. Just a few years ago lightweight refuse that rises to the ocean's surface and littered beaches created an environmental crisis and another incentive for ceasing ocean dumping of sewage and solid wastes into the oceans.

The U.S. Congress passed the Ocean Dumping Act in 1972. To continue with such dumping, permits were required and the polluter had to demonstrate to the Environmental Protection Agency that the materials to be dumped would not "unreasonably degrade or endanger human health or the marine environment." Radiological, chemical, and biological warfare agents and high-level radioactive wastes were fully banned. The dumping of dredged materials from navigable waters was put under the regulation of the U.S. Army Corps of Engineers. Dredged material is comprised of

a mixture of sand, silt, and clay, but can include rock, gravel, organic matter, and contaminants derived from a wide range of agricultural, urban, and industrial sources. As reported by R.M. Engler (U.S. Army Corps of Engineers), "Contaminated or otherwise unacceptable dredged material accounts for only a small fraction of the total—less than 10 percent in the U.S. and globally." Clean dredged waste has a number of positive uses, including the enhancement of wetlands and aquatic and wildlife habitats, beach nourishment, offshore mound and island construction, agriculture mariculture uses, and as a construction aggregate. All requests for the ocean dumping of dredged materials had to be accompanied by a list of suggested alternative actions.

As will be noted in the article on **Wastes and Pollution**, much emphasis is given to reducing pollution by creating less waste. "No Waste," of course, is an impractical target, but "Much Less Waste" can be achieved globally within the next several years, even considering major population increases. But, even then, from an economical and practical viewpoint, some scientists do not believe that the oceans can escape, in the long term, playing a major role as a "waste sink." As of the mid-1990s, both scientific and lay opinions were strongly polarized. The oceans can accommodate huge annual volumes of nonhazardous, nonfloatable wastes. Much scientific research and engineering remains to be done in removing toxic materials prior to dumping and thus protect ocean life forms and the people who eat seafood. Detoxification is mandated now prior to land dumping. Also, much more knowledge of ocean characteristics is required in the way of selecting dumping sites.

Oceanologists and waste-handling professionals presently are attempting to answer the question, "How can society use the oceans for waste disposal without harming the marine environment or fisheries resources?" Much research remains, and numerous other questions remain unanswered.

The Boston Harbor Project

For nearly a century, scores of villages (later to become cities) developed around the city of Boston, Massachusetts. The Boston Harbor and associated rivers (Charles, Mystic, and Neponset) traditionally have been used for the disposal of sewage wastes. In 1904, Boston established a centralized area sewage disposal system, which because of population expansion, has multiplied in capacity manyfold. The cities that cluster around Boston found it easier and less costly to hook into the Boston central sewage system than to build their own treating and disposal facilities. The result over the past 20 years or so has been no surprise, and Boston Harbor became known as one of the most polluted in the world. Reconstruction of the Boston sewage system commenced during the same time frame as increased state and federal regulations governing sewage disposal. Although construction of a 9.5-mile (25-km) tunnel to carry sewage wastes out of the immediate Boston harbor area to Massachusetts Bay was nearing completion as of 1994, this project serves as an interesting example of how a major environmental project can become entangled in legislation and regulatory red tape and the involvement of citizen groups in environmental issues. An excellent background description is contained in the Spring 1993 issue of *Oceanus* magazine.

The waste-transporting tunnel was bored through bedrock that supports the seafloor of Boston Harbor and Massachusetts Bay. With exception of the tunnel bored under the English Channel, it was the major tunneling project to take place during the 1980s and 1990s. Toward the end of the tunnel, a series of 55 vertical effluent discharge pipes release the sewage into the bay.

Further Quantification of Ocean Data Needed

Factors[2] that remain to be studied concerning the oceans in terms of waste disposal include:

Physical—Diffusion, advection, sedimentation.
Chemical—Volatilization, neutralization, precipitation, flocculation, adsorption, desorption, dissolution, oxidation.
Benthic—Geochemical, biological.

Over the past several decades, oceanographers have found that the oceans and seas are not as uniform as once contemplated, ranging with regard to their latitudinal and longitudinal locations and also with depth. This suggests, then, that various areas of the ocean may be more suited to accept anthropogenic debris than others. For example, temperature profiles, depths, thermal gradients, and numerous other physical, biochemical, and life-sustaining qualities are known to exist.

An early appreciation of natural oceanic detritus is given by biologist Rachel Carson, who in 1950 observed in her book, *The Sea Around Us*, "When I think of the floor of the deep sea, the single overwhelming fact that possesses my imagination is the accumulation of sediments. I see always the steady, unremitting, downward drift of materials from above, flake upon flake.... For the sediments are the materials of the most stupendous 'snowfall' the earth has ever seen." Fine particles are sinking into the global oceans every microsecond of the day and night. Such particles may include "shreds and motes and globs of stuff"—dead and decayed remains of plants and animals, meteorites and other cosmic dust, old lobster molts, volcanic fallout, radioactive fallout, the pollen from flowers, grains of sand from the deserts—in summary, just about everything that is airborne contributes to oceanic detritus. The rate of passage of suspended material from the ocean's surface to the bottom of the sea varies widely, but some scientists estimate that for some particles it may take thousands of years to reach the ultimate deep-sea graveyard. It is only in recent years that some oceanologists have studied this phenomenon seriously. Some detritus never may reach the sea floor because it is consumed by various forms of ocean life as food. A. Aldredge and M. Silver (University of California) observe, "Marine snow particles are typically smaller than a pinhead. However, in Monterey Bay off California (and probably elsewhere), the particles may be 4 inches (10 cm) across. These particles are usually aggregates of many smaller particles that stick together, often with mucus.... The largest type of marine snow is the *giant house*, which can be 6 feet (1.8 meter) across. Each house is a blob of mucus that has been secreted by a zooplankter. Some investigators refer to them as "floating islands.... While a single zooplankter inhabits its balloon of mucus, there may be hundreds of copepods on its exterior, apparently grazing on the nourishing tidbits of *marine snow*.... We find typically that *marine snow* hosts organisms in very high concentrations.... There are certain groups of organisms that seem to be found only on these.... Among the unusual characters are rare species of copepod, certain protozoans and a unique assemblage of bacteria.... *Marine snow* is a major means by which material reaches the ocean floor, a major vehicle for the transport of organic matter down to the ocean's interior.... As these particles sink through the water, they change continuously, as do the communities living on them."

Scientists have observed that *marine snow* can be a nuisance. Because in some cases gas may be produced, particles rise and create a scum, and this can be dried by the sun to produce a surface of sufficient strength to permit seagulls to walk upon it. Such scum extends for many thousands of acres (hectares) in the Adriatic Sea, where it has become a menace to fishermen and the tourist trade. Such scums were reported as early as the 1700s.

Natural Pollution of the Oceans. Frequently overlooked is what may be termed "natural" pollution, which, when coupled with artificial (anthropogenic) pollution, contributes to the sum total of all pollutants found in fresh and ocean waters worldwide. Deep fissures in the ocean floor, fumaroles, and seamounts (underwater volcanoes) release megatons of sulfur-laden and other noxious gases into ocean water; other discontinuities in the ocean basins release vast quantities of crude oil and other hydrocarbons. Surface volcanoes are major contributors to atmospheric pollution, much of which ultimately affects Earth's hydrosphere. The present dissolved solids content of the oceans represents natural water pollution that has taken place ever since the land masses rose above sea level—through a constant erosion of soil.

Oil and Hydrocarbon Pollution of the Oceans

Petroleum is not a substance foreign to the marine environment. Natural seeps have been discharging petroleum hydrocarbons into the marine environment for millions of years, in amounts substantially greater than those resulting, for example, from present offshore production activities. About 200 submarine oil seeps have been identified worldwide. There is little doubt that many more exist. Petroleum has also continuously entered the seas as a result of erosion of uplifted sedimentary rocks containing trace amounts of petroleum hydrocarbons. There is also evidence of organisms living in the ocean that biologically produce hydrocarbons, ranging from gases (methane, ethane) through liquids, to solid paraffin waxes of high molecular weight.

[2] As suggested by I.W. Duedall (Florida Institute of Technology).

These substances enter the marine environment from a variety of sources, both through natural phenomena and anthropogenic activities. In 1985, the National Academy of Sciences (NAS) published an assessment of petroleum pollution of the world's oceans and estimated that between 1.7 and 8.8 million metric tons per annum (mta) of oil enter the oceans. Within this range, 3.2 mta is regarded as the best single estimate—equivalent to about 0.1% of the total oil produced annually worldwide (about 3 billion metric tons).

Table 3 compares these estimates with those published by NAS in 1972. All categories except spills show about a 50% decrease. According to the NAS, part of the reduction in most categories can be attributed to refinements in estimating techniques. Other reductions, however, are attributed to efforts to reduce oil pollution, such as the international program to reduce tanker operational discharges. Because annual Figures for marine accidental spills vary significantly, an average over a number of years was used for both the 1975 and 1985 reports. The increase shown for such spills in the 1985 study reflects the influence of major incidents—such as the loss of the 220,000 dead-weight-ton tankers *Amoco Vadiz*, which occurred in the period (1975 through 1980)—used to calculate its annual average. The Alaskan oil spill (1989) is discussed later.

Most surface and near-surface open ocean waters contain petroleum hydrocarbons in the range of about 1 to 10 parts per billion (ppb), according to the NAS 1985 study. In deeper open ocean waters, the concentrations are 1 ppb or less. (One ppb is equal to about one drop of oil in 100,000 quarts of water.) Coastal waters, particularly those near populated and industrialized areas where the presence of oil is most likely, show higher levels (up to 100 ppb). Laboratory experiments conducted to determine the toxicity of crude oils or petroleum products indicate that concentrations from 10 to 100 times greater than those of coastal waters are required before measurable effects on marine organisms can be detected.

TABLE 3. PETROLEUM INPUTS TO THE OCEANS FROM DIFFERENT SOURCES

Source	1975 Study[1]	1985 Study[2]
	(Million metric tons annually)	
Municipal and Industrial Wastewater		
Discharges and Runoffs	2.5	1.0
Refinery Wastewater Discharges	0.2	0.1
Offshore Oil Production	0.08	0.05
Marine Transportation		
Tanker Operations	1.3	0.7
Accidental Spills	0.2	0.4
Other Maritime Activities	0.6	0.4
Natural Seeps and Erosion	0.6	0.25
Atmospheric Fallout	0.6	0.3
	6.1	3.2

[2] Oil in the Sea: Inputs, Fates, and Effects, National Academy of Sciences, 1985.

The process whereby an oil slick from a sudden spill is ultimately disposed has been the subject of intense research. Figure 4 depicts the processes occurring in the water, the overlying atmosphere, and the underlying bottom sediments. Figure 5 relates the time following discharge of oil into the sea to the various processes of movement and degradation. These processes include:

Drift. The movement of the center of a mass of oil on the surface of the ocean, drift, is caused by the combined action of wind, surface currents, waves, and tides. With larger amounts of oil, such as occur with accidental spills, the oil drift is largely independent of spill volume, spreading, or weathering. Since the "thick" portion of the slick drifts faster than the "thin" portion, a heavy oil accumulation forms the leading edge of an advancing slick. The drift process is always active—from the moment oil is released into the sea until the oil disappears from the surface. It is difficult to predict precisely all the complex interactions of oceanographic and meteorological factors that influence drift of an individual oil slick. However, field and laboratory observations of oil slick drift are surprisingly consistent.

Evaporation. The primary weathering process involved in the natural removal of oil from the sea is evaporation. It is particularly dominant soon after oil is released. Evaporation involves the transfer of hydrocarbon components from the liquid oil phase to the vapor phase. Estimates from major spills as well as experimental data indicate that evaporation may be responsible for the loss of up to 50% of a surface oil slick's volume during its life. Evaporation rates of oil at sea are determined by wind velocity, water and air temperatures, sea roughness, and oil composition. Some of the light, low-boiling hydrocarbons, such as benzene, toluene, and xylenes, which are rapidly lost through evaporation, are the most toxic. Thus, their removal decreases toxicity to marine life of the oil remaining on the surface.

Photooxidation. Much of the oil that evaporates is photo-oxidized in the atmosphere, but in the absence of good analytical data the contribution of this process cannot be estimated. It is reasonable to assume that some of the oil returns to the seas as atmospheric fallout.

Dissolution. This is another early process acting on spilled oil. Dissolution involves the transfer of oil compounds from a floating slick,

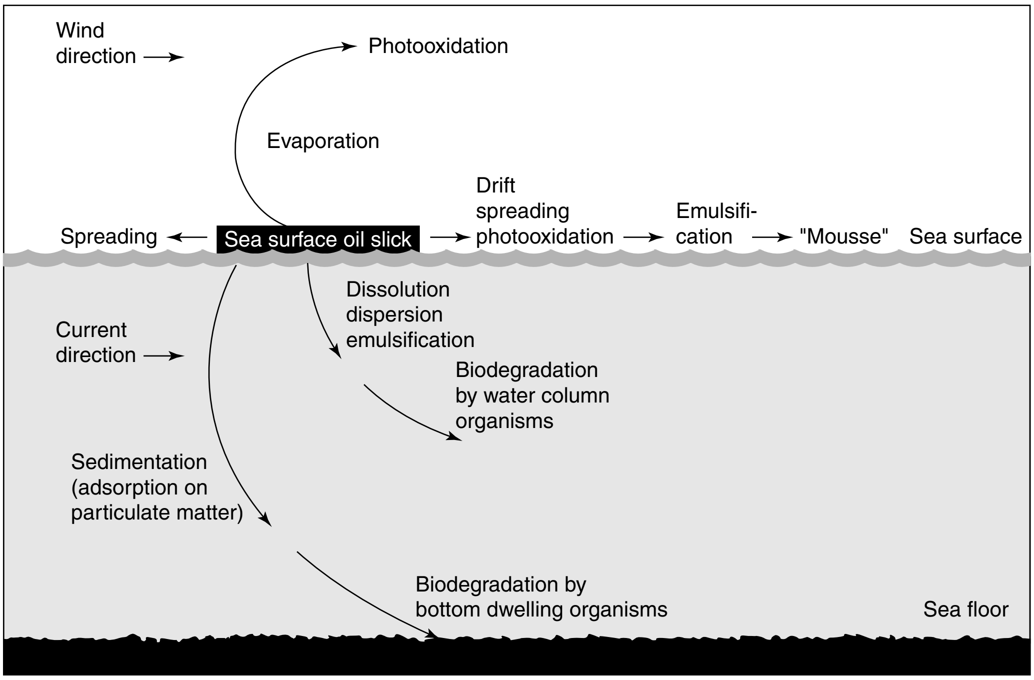

Fig. 4. Processes that act upon an oil slick

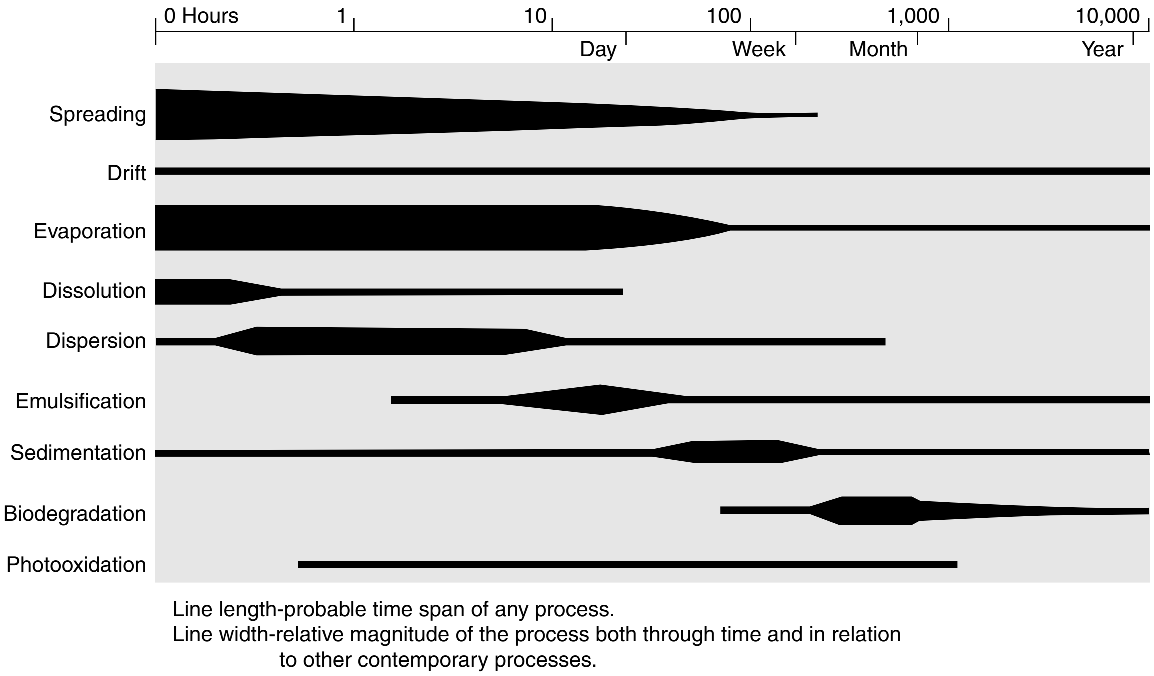

Fig. 5. Time span and relative magnitude of processes acting on spilled oil

or from dispersed oil droplets, into solution in the water phase. Lower-molecular-weight compounds tend to be the most soluble. It is unlikely, however, that dissolution significantly affects slick weathering as only a very small fraction of the oil dissolves. Evaporation proceeds much more rapidly than dissolution.

Dispersion. Oil also enters the water in forms larger than dissolved molecules. In natural dispersion, small droplets of oil (ranging in diameter from very small fractions of a millimeter to a few millimeters) are incorporated into the water in the form of a dilute oil-in-water suspension. Natural dispersion reaches a maximum rate in only a few hours (4 to 10) following a spill, but continues for some time. Oil dispersion is influenced by oil composition (e.g., wax and asphaltene content), density, viscosity, oil-water interfacial tension, and water turbulence. Crude oils and many petroleum products contain trace amounts of nitrogen, sulfur, and oxygen-bearing organic compounds, which can act as natural surfactants. These surfactants reduce the oil-water interfacial tension, allowing the oil to break up and to disperse into droplets more readily. Chemical dispersants may be applied to an oil slick to supplement the natural surfactants, thereby enhancing the dispersion process. The primary purpose for removing oil from the surface through dispersion is to enhance the degradation process. The increase in the surface area of dispersed oil droplets resulting from surfactant action accelerates the degradation of oil. Accelerating the dispersion process through the use of chemical dispersants also reduces the threat of floating oil stranding on a shoreline, where it can damage biota and property.

Emulsification. This is a water-in-oil process in which water is incorporated into the floating oil. Such emulsions, which may contain from 20 to 80% water, are often very viscous and referred to as "mousse." Mousse formation is highly dependent on oil composition. High levels of asphalt-type compounds, as well as waxes, appear to promote the formation of these emulsions. Ocean turbulence also accelerates mousse formation, although a fully developed, stable emulsion may be formed from some oils under relatively quiescent open-water conditions. Early treatment of spilled oil with chemical dispersants is an excellent way to prevent emulsification.

Sedimentation. Some organisms may ingest dispersed oil droplets in the water column and subsequently deposit them as fecal pellets. In some instances, this has been estimated to be a significant form of sedimentation.

Biodegradation. This is an important process for removing petroleum hydrocarbons from the marine environment. All surface waters, fresh or marine, contain natural populations of bacteria, yeast, and fungi capable of metabolizing and chemically degrading hydrocarbons through their normal life processes. These organisms are also primarily responsible for degrading most of the biologically produced hydrocarbons in the ocean. The rate and extent of biodegradation depend on the abundance and variety of existing microorganisms, their predators, available oxygen and nutrients, temperature, and oil composition. Hydrocarbons, dissolved or dispersed in water, are the most easily degraded. Degradation of hydrocarbons contained in bottom sediments also occurs if oxygen is present. Emulsified oil (mousse) is slow to degrade because water is trapped within the emulsion and the nutrients and oxygen essential to biodegradation are kept out.

Invention of Oil-Eating Bacterium. It is interesting to note that the concept of genetically altering bacteria to transform crude oil into cattle feed was proposed by A.M. Chakrabarty (General Electric Co.) in the late 1960s. A patent was not granted until 1980 after considerable litigation. The concept is considered by many as the cornerstone of the biotech industry. Chakrabarty as of the 1990s continues in this field. Although applications in other areas of the petroleum industry may find applications for such bacteria, the primary interest in recent years has been in connection with oil tanker spill cleanups.

After the Alaskan oil spill of March 1989, approximately 70 miles (113 km) of beaches around Prince William Sound were sprayed with a fertilizer (*Inipol*) that had been invented by a French petroleum company (*Elf Aquataine*). The effort was made to stimulate the growth of naturally occurring bacteria (i.e., microorganisms that eat petroleum). This was the first large-scale test of bacteria for cleaning up an oil spill. Improvement was noted within a couple of weeks after the spraying. Research continues with the material to determine its effectiveness on shoreline rocks and pebbles. Early findings indicated that oil caught beneath the surface of rocks was consumed in 6 to 7 weeks. Researcher C. Oppenheimer (University of Texas) also developed microbial strains for producing fatty acids from oil, the product of which is more soluble in water. These compounds serve as food for plankton and other organisms.

Oil Tanker Spills

Usually the most publicized and one of the most dramatic examples of ocean water (and adjacent shoreline) pollution involves oil tanker or barge accidents. Most often, the saline waters of the oceans and seas are polluted, although there are instances where such accidents have occurred in fresh and brackish waters.

Oil spills present many different variations in the manner in which they develop and react to cleanup efforts. The Alaskan spill that occurred on March 24, 1989, in Prince William Sound was the most extensively researched to date. The cost of cleaning up the spill also exceeded all other tanker spill expenses to date. A study reported by the U.S. Forest Service estimates the final fate of the 10 million gallons as follows: evaporated, 35%; recovered, 17%; burned, 8%; biodegraded, 5%; and dispersed, 5%.

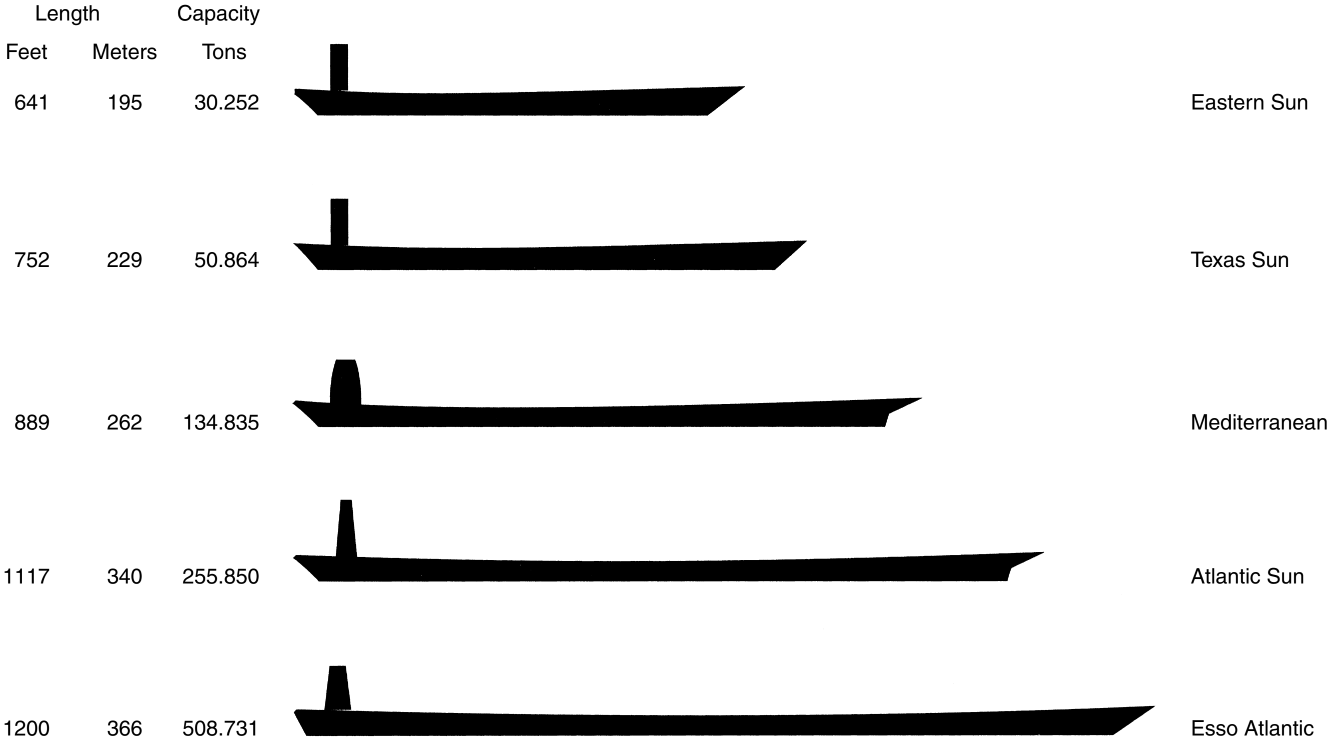

Fig. 6. Trends in oil tanker design characteristics. (*After A. Dane*)

The total in the form of oil slicks on the Sound amounted to about 10% of the original spill and that on the shoreline about 18%. For many weeks after the spill, a fleet of specially equipped vessels mopped up about 120,000 gallons of crude oil per day. Other tanker spills have carried crude oil of somewhat different composition. The state of the sea, temperature, winds, and presence or absence of sunshine are among other variables that make each spill unique.

Tanker Design. One ship designer has observed that modern tankers are uniquely fragile and unwieldy vessels. The goal of tanker design is "to get as much cargo as you can into as little steel as possible and still have economical propulsion." Thus, the larger the ship, the easier to meet these specifications. Ultra-large crude carriers (ULCCs) required a distance of 3 miles (4.8 km) and about 20 minutes to stop from a top speed of 15 to 16 knots. Oil tankers have steadily increased in capacity and length over the last few decades. See Fig. 6.

Because of several major tanker incidents over the last few years and highlighted by the Alaskan spill, much design thought has gone into the "double-hull" concept. Indeed, this is not a new concept because two "skins" are used on the nearly 60,000 merchant vessels afloat—with the important *exception* of oil tankers. Double hulls have been standard on liquefied natural gas (LNG) ships for many years, and the design has been credited with preventing disasters at sea. The double-hull design enabled one LNG ship to sail many miles at its highest speed to the nearest port even though the outer hull had been torn open under several of the cargo tanks. None of the highly volatile cargo escaped.

The oil industry has objected to two hulls for the following reasons:

1. If oil leaked from the inner to the outer shell, the space in between could generate a vapor and thus be an explosion hazard.
2. When the outer hull was breached by an accident, water would fill the void, causing the ship to lose buoyancy and possibly go aground.

Even with these objections, there are some 530 oil tankers with double hulls, and these have been accident-free thus far.

Other improvements in tanker design have included more precise navigation systems that are customized to the vessel and the coarse of travel that it usually follows. In a single video readout are shown the ship's location and course with respect to shoreline, bottom contours, buoys, markers, and other ships. With another system, which includes radar reflectors located along the shoreline, the ship location can be determined within less than about 6 feet (1.8 meters). Another concept embraces use of a funnel that can be lowered from the ship immediately when a spill occurs and sucks the spilled oil back into the ship. A design of this kind has been under test in the Gulf of Mexico.

Radioactive Waste Dumping. Numerous proposed solutions for dumping radioactive wastes, including ocean burial, are described in the article on **Nuclear Power Technology**.

WATER RESOURCES. As pointed out by various authorities, major problems pertaining to water, in addition to pollution, include: (1) the heavy consumption, which began some years ago to limit the growth of various cities and of agriculture, particularly in the southwestern United States; (2) evaporation losses from reservoirs and storage ponds, particularly important in the arid western and west central sections of the United States, the control of which may be found to be more economic than that of developing new water sources; (3) lowering water Tables, again of major concern to the southwest and Pacific coastal regions of the United States, but also becoming a major factor near larger cities, and to some middle-Atlantic areas of the United States, a situation which is exerting considerable influence on the choice of new irrigation areas; (4) long-distance water transmission systems, which in the future may not be confined to the western United States; (5) waste water return to the oceans, which can become the largest and least expensive potential secondary water source and a very attractive source for many industrial uses; (6) salt water encroachment, which already is destroying some water sources and land; (7) watershed trash vegetation, the eradication of which can increase water yield, particularly in the southwestern United States; and (8) storage of seasonal and flood flows, which has been practiced for many years in most areas that are away from good lake or groundwater supplies, but which will require extension as the water problem becomes more severe in the less-arid areas.

The water supply problems of the United States image those of many other areas of the world. As is evident from Fig. 1, the eastern one-third of the United States, excepting a few areas and several of the major cities, does not generally run a seasonal water deficiency. Somewhat over one-third of the western United States, however, is characterized by no available surplus, and other areas by summer deficiency and winter surpluses.

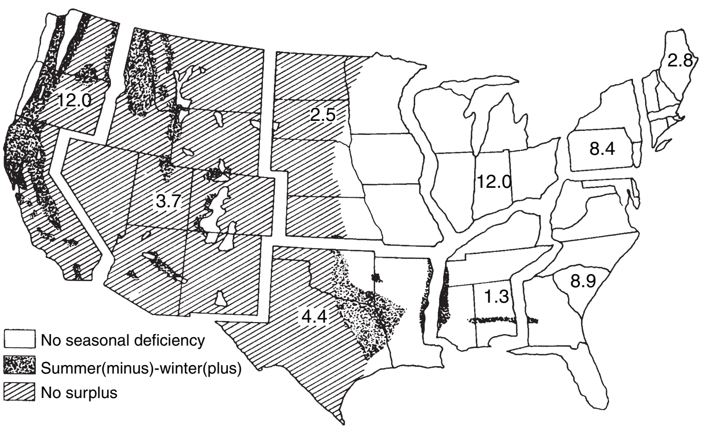

Fig. 1. Water supply versus population increases. Figures indicate expected increases (millions of people) by the year 2000. (*U.S. Department of the Interior*)

Water resources must be evaluated in the long term because unusually wet or dry winters (such as 1980–1981), while of near-crisis proportions, do not represent the average of a decade or more. What is important is to watch trends that appear to be consistent.

Widespread flooding in the midwestern United States during the summer of 1993 is regarded by some experts as a 1 in 100 year experience. Every century experiences a few weather phenomena that statistically contribute to the minimums and maximums of data, but do not necessarily predict any permanent changes in the weather picture for a given region. Final analyses of data from the 1993 flooding will not be completed for another year or two.

The environmental problem of finding additional sources of clean water have some parallels with the problem of finding new ways for disposing of wastes. These are indeed limited. Again, the subject of *waste reduction* enters into the picture. Whereas, fundamentally, pollution equates with cutting back on the production of wastes, water shortages equate markedly with reducing the waste of water. This, too, presents a variety of sociological preferences and concerns. Persons who live in communities where water shortages approach near-crisis proportions are fully aware of how inconvenient it is to cut back on water consumption. Over the years, a few imaginative suggestions have been made. Weather alteration in an effort to produce rain essentially has been abandoned by technologists. Dam building, in addition to creating hydroelectric power, also contributes to smoothing out the water supply for many regions. In recent years, however, a substantial citizen's movement against creating dams has arisen.

Although nearing the fantasy level, icebergs have not been ruled out technically as "portable and potable" sources of excellent water.

While desalination now serves a number of the arid regions of the world (see also **Desalination**) and the costs of desalination have been reduced because of improved processes, the economics of processing discourage the use of desalination in the less arid regions of the world. However, if the world's population continues to expand geometrically, the price per gallon or liter of drinking water, for example, may rise beyond belief.

Water from Icebergs

The concept of obtaining fresh water from icebergs dates back many years. One of the earlier proponents was Isaacs (Scripps Institute of Oceanography) who described the concept in the 1940s. The concept has been characterized by a cycling of interest over the years, but with little follow-through among world scientists and planners. In 1977, the first conference on iceberg utilization of major proportions was held at Iowa State University, with over 200 scientists, consultants, and representatives of private firms from 18 nations present to consider the technical, economic, environmental, and legal problems that may be involved in transporting and exploiting icebergs. In discussions over the last several years, most attention has been given to icebergs from the Antarctic rather than the Arctic region, principally those icebergs that break away from the Ross Ice Shelf.

Melted water from an iceberg is extremely pure, with only traces of rock fragments and with almost complete absence of trapped organic matter. Contamination has been estimated at one part per billion and thus far superior to other fresh water unless it is distilled. The Iowa State conference was financed in part by the National Science Foundation and Saudi Arabia.

In contemplating the possible use of icebergs as a future source of fresh water, it is interesting to note that although there are about 1.4 billion cubic kilometers of water on Earth, only about 9 million cubic kilometers (six-tenths of one per cent) of the total is both liquid and fresh. The useful supply tends to be about 10–20% of the total precipitation per year, or about 10,000–20,000 cubic kilometers.

The ice sheet in the Antarctic accumulates an input of precipitation equivalent to about 2000 cubic kilometers of water per year. About half of this total forms into tabular (flat) icebergs, each equivalent to about 200 cubic kilometers of water. The slabs are from 200 to 250 meters thick and up to about 0.5 kilometer wide. Greenland icebergs, in contrast, are more irregular in shape and size. Antarctic icebergs would have to be transported about 4,000 miles (6,436 kilometers) to the southwestern coast of Australia; about 9,500 miles (15,286 kilometers) to southern California; and about 12,000 miles (19,308 kilometers) to the Middle East. Several studies have been made as regards towing icebergs and the consensus is that the technology for this already exists. Towing of some icebergs already has been done in connection with oil drilling activities, where tugs are used to deflect Greenland-originated icebergs from the path of drillships and platforms. Also, many attempts have been made to destroy (break up) icebergs through the use of explosives to prevent the icebergs from drifting into major sea lanes. These experiments have largely been unsuccessful because one kilogram of explosive will break up only about 4 cubic meters of ice. Even though ice possesses a low strength and density, it reacts to blasting much like ordinary rock.

During the 1990s, the use of icebergs as a source of fresh water remained a topic of considerable conjecture. Topics discussed at the Iowa State Conference included: (1) use of earth resources satellites to find the most suitable icebergs for this purpose; (2) study of various transportation modes, such as tugs for pulling, semi-submersibles and submarines for pushing, and propellers mounted on icebergs to make them self-transportable; (3) ways to minimize melting during transport, e.g., stretching plastic sheets over the iceberg or spraying its surface with urethane foam; (4) investigation of legal problems relating to ownership of Antarctic ice; (5) the numerous environmental effects which such actions might provoke; (6) possible use of icebergs as energy sources, through harnessing of thermal and salinity gradients. If the concept takes hold, it would seem that the first tests would be conducted in the Southern Hemisphere.

For further details, see "The Iceberg Cometh," by W.F. Weeks and Malcolm Mellor, *Technol. Rev.* (*MIT*), pp. 66–75 (August/September, 1979), and *Science*, **198**, 274–276 (1977).

Many of the scientific aspects of water resources are described in several entries in this encyclopedia. See also **Connate Water**; **Desalination**; **Groundwater** and **Water Pollution**.

WATER SOLUBLE POLYMERS. Water-soluble polymers find application in a wide variety of areas that include polymers as food sources, plasma substitutes, and as diluents in medical prescriptions. Other areas of importance for water-soluble polymers include detergents, cosmetics, sewage treatment, stabilizing agents in the production of commodity plastics, rheology modifiers in the various processes for petroleum, textile, paper, and latex coatings production. The water-soluble polymers discussed in this article have significant commercial impact.

Hydrophilic Groups. Water solubility can be achieved through hydrophilic units in the backbone of a polymer, such as O and N atoms that supply lone-pair electrons for hydrogen bonding to water. Solubility in water is also achieved with hydrophilic side groups (e.g., OH, NH_2, CO_2^-, SO_3^-). Truly unique in its ability to interact and promote water solubility is the $-O-CH_2-CH_2-$ group. The interactions of these groups with water and their placement in the polymer structure influence the water solubility of the polymer and its hydrodynamic volume.

Viscosity Efficiency. A majority of the applications of water-soluble polymers revolve around their role in increasing the viscosity of water solutions. The hydrodynamic volume of the polymer influences its viscosity efficiency, and thereby its ability to modify the rheology of an application formulation. The primary parameter influencing the hydrodynamic volume is the polymer's molecular weight. The second is in the conformational rigidity or extension of the polymer chain in solution. For example, carbohydrate polymers contain repeating ring structures that facilitate a more rigid structure than observed in non-ionic synthetic polymers. At a given molecular weight this effects a greater viscosity efficiency. The rigidity also can be increased by inclusion of charged groups in both synthetic and carbohydrate polymers. Such groups lead to electrostatic repulsions and extension of the chain in deionized aqueous solutions and an increase in the hydrodynamic volume of the polymer. Greater rigidity also can be achieved in carbohydrate polymers if helical conformations are realized.

Carbohydrate Polymers

An anhydroglucose ring or glucopyranosyl unit (Fig. 1**a**) is the structural unit on which human metabolism is dependent. The anhydroglucose unit provides, through the four hydroxyl units, a diversity of polymer structures that can be formed through variations in positional bonding between the rings (i.e., $1 \rightarrow 2, 1 \rightarrow 3, 1 \rightarrow 4$, and $1 \rightarrow 6$). Examples of different positional bonding in carbohydrate polymers are illustrated in Figure 2.

Symmetrical $1 \rightarrow 4$ bonding provides the world's most abundant polymer, cellulose (Fig. 2**a**). The bonds linking hydroxyl units in the plane of the puckered ring are referred to as equatorial bonds. The glucopyranosyl unit is also present in amylose (Fig. 1**b**). The variance between cellulose and amylose (the latter is a component of starch) is in the interunit bonding between anhydroglucose rings. In cellulose, the rings are connected through equatorial–equatorial bonding (beta-linkage); in amylose the $1 \rightarrow 4$ inter-ring bonding is equatorial–axial (alpha-linkage; axial denotes a bond perpendicular to the general plane of the ring). The beta-linkage in cellulose, complemented by the intrahydrogen bonding among rings facilitates a linear projection of the polymer. This,

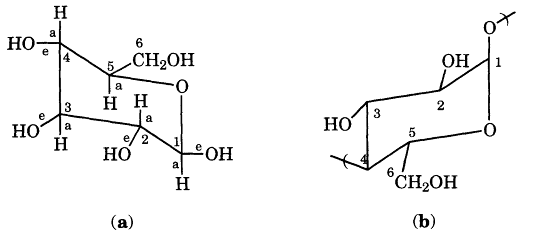

Fig. 1. (**a**) The glucopyranosyl basic unit, where e = equatorial and a = axial bond; (**b**) amylose with equatorial–axial interunit bonding (the C–H axial bonds have been omitted).

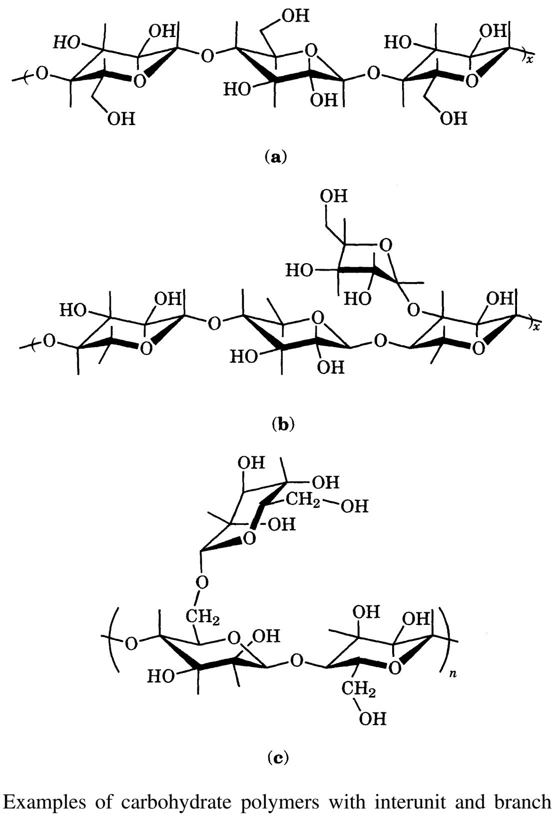

Fig. 2. Examples of carbohydrate polymers with interunit and branch position differences: (**a**) cellulose; (**b**) flaxseed gum; (**c**) guaran

complemented by interhydrogen bonding among polymer chains, provides crystallinity and a rigid structure. To transform the world's most abundant polymer, cellulose, into a water-soluble species requires replacement of some of the hydroxyls to disrupt the extensive hydrogen bonding.

Amylose (Fig. 1**b**), with alpha-interconnecting linkages, is soluble in hot water, (unlike cellulose), but it retrogrades in low-temperature aqueous solutions into a helical conformation and precipitates. Glucopyranose branching from the C-6 hydroxyl provides solubility at low temperatures. Thus this anomeric bonding difference (i.e., alpha-(1 → 4) instead of the beta (1 → 4) linkage in cellulose) provides a readily accessible source of energy and is designated as a storage source in nature.

The anomeric difference (i.e., the alpha- and beta-linkages) between cellulose and amylose is important. Of greater importance in determining the aqueous solution properties of water-soluble polymers is the interunit bonding patterns between rings. As with amylose, branches from the C-6 position promote solubility in water. Two naturally occurring carbohydrate polymers with structural main chain similarity to cellulose (i.e., in the beta-(1 → 4) linkage), but with water solubility without derivatization due to side branch units, are the nonionic fraction of flaxseed gum and guaran (Fig. 2**b** and 2**c**, respectively).

Cellulose

Commercial Derivatization of Cellulose. Cellulose, the world's most abundant polymer, is derivatized for use in a variety of markets. Cellulose ethers are an important segment of water-soluble polymers.

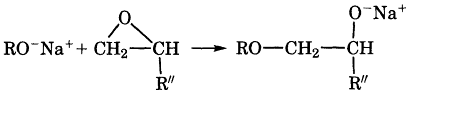
Commercial derivatization of cellulose begins with the addition of sodium hydroxide to form alkali cellulose (AC) (eq. 1, R = carbohydrate).

$$ROH + NaOH \rightleftharpoons RO^-Na^+ + H_2O \qquad (1)$$

The AC may react with methyl chloride or alpha-chloroacetic acid via a direct displacement reaction (eq. 2). The derivatives would be methyl cellulose or carboxymethyl cellulose.

$$RO^-Na^+ + R'X \longrightarrow ROR' + NaX \qquad (2)$$

Alternatively, the AC may react with oxiranes e.g., ethylene oxide (R″ = H) or propylene oxide (R″ = CH_3) (eq. 3).



(3)

The derivatives are hydroxyethyl and hydroxypropyl cellulose. All four derivatives find numerous applications, and there are other reactants that can be added to cellulose, including the mixed addition of reactants leading to adducts of commercial significance. See also **Cellulose Ester Plastics (Organic)**.

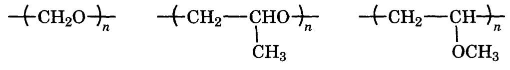
Biosynthesis. Although cellulose can be derivatized, such materials do not provide the optimum properties desired in many applications, such as retention of viscosity at higher solution temperatures, greater mechanical stability, and greater thickening efficiency. These properties can be approached with carbohydrate polymers in helical conformations, which can be achieved in some carbohydrate polymers prepared by fermentation processes. Yeasts have an advantage over fermentation processes using bacteria, because the fermentation can be conducted in low pH media. Yeast are also larger and easier to remove by filtration. However, the most successful commercial fermentation polymer is XCPS, synthesized by a bacteria, *Xanthomonas campestris*. In this polymer the main chain is simply cellulose, but with three pyranosyl rings branched from the C-3 position of every other repeating ring. This arrangement promotes a helical conformation. See also **Yeasts and Molds**.

Recently, two fermentation polymers have produced optimum properties through variations in positional and interunit bonding patterns: gellan and wellan.

Other Considerations. With multiple hydroxyl units on every repeating ring, most commercial carbohydrate particles are surface treated with glyoxal. After adequate dispersion of the particles in water, a small quantity of base solution is added to remove the acetal cross-linked structure. The individual particles then readily hydrate without the agglomeration of partially hydrated particles before complete hydration is achieved. The segmentally rigid and conformationally rigid (in helical polymers) ring structures provide a more viscous aqueous shear viscosity, but lower extensional solution viscosity for a given molecular weight. The rigidity provides greater mechanical stability relative to synthetic polymers discussed below.

Synthetic Water-Soluble Polymers

Polyoxyethylene. Synthetic polymers with a variety of compositionally similar chemical structures are as follows. Based on polarity, poly(oxymethylene) (**1**) would be expected to be water soluble. It is a highly crystalline polymer used in engineering plastics but it is not water-soluble. Polyoxypropylene (PPO) (**2**) and poly(methyl vinyl ether) (PMVE) (**3**) have



(**1**) (**2**) (**3**)

identical chemical compositions; PMVE is water soluble up to a modest temperature (~50°C), but PPO is not soluble in water. PPO is soluble only in the oligomeric form with less than 10 PO units. PO defines oxypropyl or propylene oxide monomer overcome the terminal hydroxyl groups facilitating water solubility when there are more than 10 repeating units. In view of the lack of water solubility of two compositionally similar polymers, the water solubility of polyoxyethylene POE (**4**) is notable. It occurs because of the unique interaction of water with the oxyethylene chain.

(**4**)

Polyoxyethylene (POE) is synthesized employing different catalyst systems depending on the desired mol wt. For molecular weight below 20,000 (generally referred to as poly(ethylene glycol)s, PEGs), base or the Na^+ or K^+ alkoxides of methanol or butanol are used. Without the numerous hydroxyls present in carbohydrate polymers, POE particle structures cannot be treated to minimize their hydration prior to dissolution. The particle surfaces are covered with silica to minimize hydration and blocking of POE particles on storage. POE and PEGs of various molecular weights have found numerous applications.

Commodity Chain-Growth Polymers. Two of the largest commodity water-soluble polymers are poly(vinyl alcohol) (PVA) and polyacrylamide (PAM). They are prepared by the free-radical initiation of vinyl monomers, a chain-growth polymerization technique.

Poly(vinyl alcohol). The vinyl alcohol monomer is unstable and isomerizes to acetaldehyde. The polymer is obtained by the hydrolysis of poly(vinyl acetate). The vinyl acetate monomer produces a very high energy radical during chain-growth propagation. This accounts for the high chain transfer to monomer, a higher than normal head to head addition of propagating species, and grafting of some of the propagating species to polymer that is formed during an earlier stage of the polymerization. This leads to a more complex variation in structure than observed in PAM polymers, and this, with the differences that are realized with different methods of hydrolysis, can result in different Poly(vinyl alcohol) (PVA). These factors, on hydrolysis, lead to PVA below 50,000 molecular weights. See also **Vinyl Acetal Polymers**.

PVA is isomeric with POE; however, it can enter into hydrogen bonds with both water and with the other hydroxyl units of the repeating polymer chain, forming both inter- and intrahydrogen bonds. The extensive hydrogen bonding can lead to crystallinity, an occurrence that complicates its water solubility. Commercial PVA is essentially atactic. With most chain-growth polymers, crystallinity is associated with stereoregularity, but the small size of the hydroxyl substituent group promotes crystallinity even in the atactic polymer. For this reason poly(vinyl acetate) is seldom hydrolyzed completely; it is manufactured retaining three acetate levels: 25, 12, and 2 mole percents (these numbers represent averages). With higher acetate percentages the polymer is more surface active, which is important in its role as a suspending agent in poly(vinyl chloride) commodity resin production. Also, it is readily soluble in water at ambient temperatures. With low acetate percentages, PVA is difficult to dissolve unless the water temperature is high, and on cooling the low acetate PVA may precipitate.

Hydrolyzed Polyacrylamide. HPAM can be prepared by a free-radical process in which acrylamide is copolymerized with incremental amounts of acrylic acid or through homopolymerization of acrylamide followed by hydrolysis of some of the amide groups to carboxylate units. The

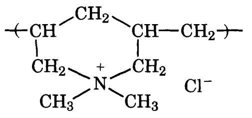
carboxylated units, ionized, decrease adsorption on subterranean substrates, in proportion to the number of units, an important parameter in petroleum recovery processes. In waste treatment processes cationic acrylamide comonomer units are often used to increase adsorption and thereby flocculation of solids in wastewater. See also **Acrylamide Polymers**. Because the synthesis of HPAM can be conducted in water, the problem of dissolution in many applications is addressed by polymerizing the monomer in water-in-oil emulsions.

Poly(vinyl pyrrolidone). Another commercial polymer with significant usage is PVP. It was developed in World War II as a plasma substitute for blood. This monomer polymerizes faster in 50% water than it does in bulk, an abnormality inconsistent with general polymerization kinetics. This may be due to a complex with water that activates the monomer; it may also be related to the impurities in the monomer that are difficult to remove. See also **Vinyl Acetal Polymers**.

Poly(acrylic acid) and Poly(methacrylic acid). Poly(acrylic acid) (PAA) may be prepared by polymerization of the monomer with conventional free-radical initiators using the monomer either undiluted (with cross-linker for superadsorber applications) or in aqueous solution. Photochemical polymerization (sensitized by benzoin) of methyl acrylate in ethanol solution at −78°C provides a syndiotactic form that can be hydrolyzed to syndiotactic PAA.

Cationic Water-Soluble Polymers

Cationic monomers are used to enhance adsorption on waste solids and facilitate flocculation. One of the first used in water treatment processes (**5**) is obtained by the cyclization of dimethyldiallylammonium chloride in 60–70 wt % aqueous solution. Another cationic water-soluble polymer, poly(dimethylamine-*co*-epichlorohydrin), prepared by the step-growth

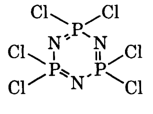


(**5**)

polymerization of dimethyl amine and epichlorohydrin, is also used for adsorption on clays.

Inorganic Water-Soluble Polymers

Two inorganic water-soluble polymers, both polyelectrolytes in their sodium salt forms, have been known for some time: poly(phosphoric acid) and poly(silicic acid). A more exciting inorganic water-soluble polymer with nonionic characteristics has been reported. This family of phosphazene polymers is prepared by the ring-opening polymerization of a heterocyclic monomer (**6**) followed by replacement of the chlorine atoms in the resultant polymer.



(**6**)

The hydrophobic inorganic backbone provides an easy route to variable water-solubilizing side nonionic or ionizing groups. These are stable to hydrolysis at room temperature.

One of the main advantages of water-soluble polyphosphazenes is the ease with which water-solubilizing side groups can sufficiently cross-link in a stable matrix with high energy radiation such as x-rays, gamma-rays, electron beams, or ultraviolet light.

The versatility of water-soluble polyphosphazenes is in the variations in the structures that can be prepared. Structures with a low glass-transition temperature backbone can be modified with a variety of versatile side units.

New Commercial Water-Soluble Polymers

Two recently developed water-soluble polymers have achieved limited market acceptance.

One product is poly(2-ethyl-2-oxazoline) (PEOX). It is prepared by the ring-opening polymerization of 2-ethyl-2-oxazoline with a cationic initiator. Most of the polymer's characteristics stem from its molecular structure, which like POE, promotes solubility in a variety of solvents in addition to water. It exhibits Newtonian rheology and is mechanically stable relative to other thermoplastics. It also forms miscible blends with a variety of other polymers. Another product is prepared from N-ethenylformamide formed from the reaction of acetaldehyde and formamide. The vinyl amide is polymerized with a free-radical initiator, then hydrolyzed.

The protonated form of poly(vinyl amine) (PVAm–HCl) has two advantages over many cationic polymers: high cationic charge densities are possible and the pendent primary amines have high reactivity. It has been applied in water treatment, paper making, and textiles.

Hydrophobe-Modification of Water-Soluble Polymers

Although many of the new water-soluble polymers discussed above have not achieved large-scale commercial acceptance, there is a class that has achieved outstanding success since the early 1980s: hydrophobically modified water-soluble polymers (HM-WSPs). They have filled certain voids in a number of applications that include cosmetic, paper, architectural, and original equipment manufacturing (OEM) coating areas and have found unsuspected application in the airplane de-icers market. The driving force for the development of HMWSPs is threefold in most application areas: 1. The achievement of high viscosities at low shear rates without high molecular weights. 2. Minimization of the elastic behavior of the fluid at high deformation rates that are present when high molecular weight water-soluble polymers are used. 3. Providing colloidal stability to disperse phases in aqueous media, not achievable with traditional water-soluble polymers.

Preparation of hydrophobically modified, water-soluble polymer in aqueous media by a chain-growth mechanism presents a unique challenge in that the hydrophobically modified monomers are surface active and form micelles.

The hydrophobe modification of acrylic acid represents an important class of hydrophobe-modified thickeners prepared by a chain-growth free-radical process. They differ slightly from other examples in that these products are generally cross-linked.

Hydrophobe-modification of hydroxyethylcellulose produces what should be considered model associative thickeners, for the distribution of hydroxyethyl units has been characterized. The commercial material, a Hercules product, contains three hydrophobes per chain.

HEUR associative thickeners are in effect poly(oxyethylene) polymers that contain terminal hydrophobe units. They can be synthesized via esterification with monoacids, tosylation reactions, or direct reaction with monoisocyanates.

WATER TREATMENT (Boiler). One of the most critical and exacting requirements for pretreating water prior to industrial use is found in connection with the operation of modern boilers. Many of the basic principles of water treatment are encountered for this application.[1] The advantages of modern boilers can be realized to the fullest only if proper attention is given to water treatment. No boiler can operate efficiently or dependably if its heat-transfer surfaces are allowed to foul with scale or if corrosion is permitted to occur.

Water treatment must include conditioning of the:

1. Raw-water supply.
2. Condensate returns from process steam or turbines.
3. Boiler water.

Proper conditioning will result in:

[1] Abstracted, with permission, from "Steam/Its Generation and Use," 39th edition, Babcock & Wilcox, New York (1978).

1. Freedom from deposits on internal surfaces.
2. Absence of corrosion of internal surfaces.
3. Prevention of carry-over of boiler water solids into the steam, caused by foaming and/or high total dissolved solids.

Some definitions of the water terminology in various parts of the boiler cycle are desirable. Steam that is condensed and returned to the boiler system is termed condensate. Steam lost due to process requirements, blowdown or leakage out of the system, has to be replaced; the replacement water added to the system is termed makeup water. The condensate together with the makeup water comprise the feedwater to the boiler. In some plants only a small percentage of condensate is returned; in others, almost all the steam generated is recovered as condensate. Feedwater enters the boiler and is evaporated into steam, leaving behind solids to concentrate in the boiler water. If the concentration of solids in the boiler water exceeds certain limits, the quality of steam can be impaired by carry-over. Also, boiler-water solids may settle out on the boiler surfaces as sludge. The concentration of solids in the boiler water can be controlled by removing a portion of the water either intermittently or continuously. This bleeding of a portion of the boiler water from the drum is termed blowdown.

In Universal-Pressure boilers, there are no drums to concentrate the boiler-water salts and impurities, and blowdown is not utilized. Purification takes place by continuously passing all or part of the condensate through demineralizers in a process called condensate polishing.

The treatment of raw water, condensate, feedwater and boiler water, and the subjects of carry-over and steam purity are considered in detail in the sections which follow.

Raw-Water Treatment

Water never exists in the pure form. All natural waters contain varying amounts of dissolved and suspended matter. The type and amount of matter in water varies with the source, such as lake, river, well or rain, and also with the section of the country.

As rain, water brings into solution the atmospheric gases of oxygen, nitrogen and carbon dioxide. As it percolates through the soil, it dissolves and picks up many minerals harmful to boiler operation. Surface waters frequently contain organic matter that must be removed before the water is satisfactory for use in a boiler.

Suspended solids are those that do not dissolve in water and can be removed or separated by filtration. Examples of suspended solids are mud, silt, clay and some metallic oxides.

Dissolved solids are those which are in solution and cannot be removed by filtration. The major dissolved materials in water are silica, iron, calcium, magnesium and sodium. Metallic constituents occur in various combinations with bicarbonate, carbonate, sulfate and chloride radicals. In solution these materials divide into their component parts called ions, which carry an electrical charge. The metal ions carry a positive charge and are referred to as cations. The bicarbonate, carbonate, sulfate and chloride ions are negatively charged and are referred to as anions.

Scaling occurs when calcium or magnesium compounds in the water (*water hardness*) precipitate and adhere to boiler internal surfaces. These hardness compounds become less soluble as temperature increases, causing them to separate from solution. Scaling causes damage to heat-transfer surfaces by decreasing the heat-exchange capability. The result is overheating of tubes, followed by failure and equipment damage.

Porous deposits will allow concentration of boiler-water solids. This concentration of boiler-water solids, particularly if strong alkalies are present, will result in severe corrosion of the tube surfaces.

Since water impurities cause boiler problems, careful consideration must be given to the quality of water in the boiler. External treatment of water is required when the amount of one or more of the feedwater impurities is too high to be tolerated by the boiler system.

The selection of equipment for raw-water preparation should only be made after a careful analysis of the raw-water composition, quantity of makeup required, boiler type and operating pressure. Generally, the first step in the water processing involves coagulation and filtration of the suspended material. Natural settling in quiescent water will remove relatively coarse suspended solids. The required settling time depends on specific gravity, shape and size of particles and currents within the settling basin. This process can be speeded up by coagulation. Coagulation is the process by which finely divided materials are combined by the use of chemicals to produce large particles capable of rapid settling. Typical coagulant chemicals are alum and iron sulfate. The preliminary treatment involves chlorination of the water for the destruction of the organic matter. Several manufacturers offer equipment to operate on a completely automated basis, as illustrated in Fig. 1.

Following coagulation, settling and chlorination, the water should be passed through filters. Filtration removes the finely divided suspended particles not removed in the coagulation and settling tanks. Special equipment such as activated-charcoal filters may be necessary to remove the final traces of organic and excess chlorine. After the removal of the suspended material in the raw water, the hardness of scale-forming materials are still present in solution. Further treatment is required to remove these materials. This treatment consists of precipitating the hardness constituents and/or exchanging the hardness for non-hardness constituents in a process called ion exchange. Brief descriptions of each of these processes follow. It is recommended that assistance by obtained from a water consultant in order to select the best process and equipment for a specific installation.

Sodium-Cycle Softening. This process, called sodium zeolite softening, utilizes resin materials that have the property of exchanging the hardness constituents, calcium and magnesium, for sodium. The process continues until the sodium ions become depleted or, conversely, the resin capacity to absorb the calcium and magnesium no longer exists. When this occurs, the resin is said to be exhausted, and is regenerated by passing a solution of salt through it.

Water, after passing through the zeolite process, contains as much bicarbonate, sulfate and chloride as the raw water, only the calcium and magnesium having been exchanged for the sodium ions. There is no

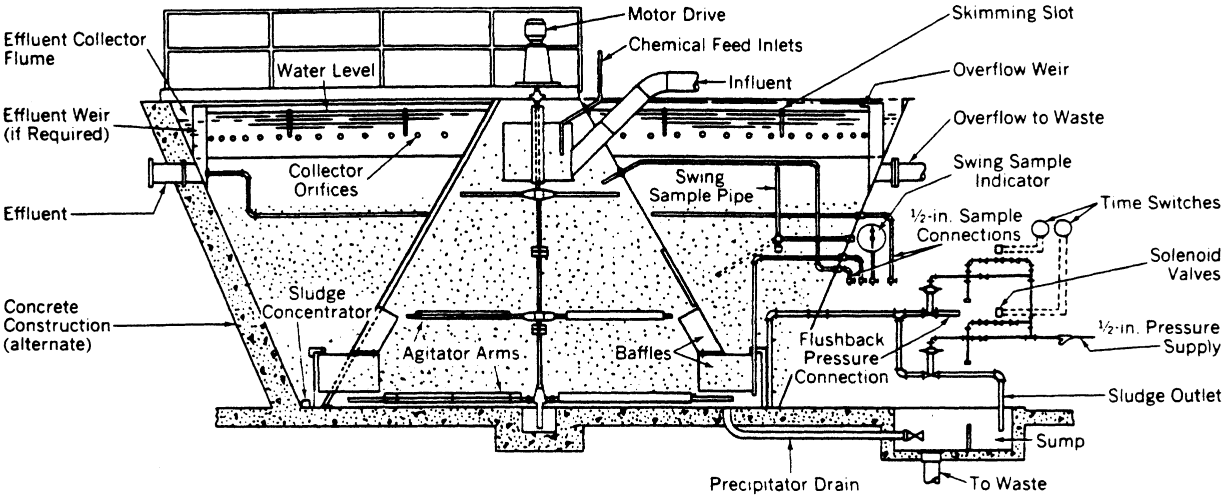

Fig. 1. Sludge contact softener. (*Betz "Handbook of Industrial Water Conditioning."*)

reduction in the overall amount of dissolved solids and neither is there a reduction of alkalinity content. When it is necessary to reduce the amount of total dissolved solids, zeolite must be coupled with other methods such as hot lime zeolite softening. The reduction of alkalinity is discussed under *Hot Lime Zeolite–Split Stream Softening*.

Hot-Lime Zeolite Softening. In this process hydrated lime is employed to react with the bicarbonate alkalinity of the raw water. The precipitate is calcium carbonate and is filtered from the solution. To reduce silica, the natural magnesium of the raw supply can be precipitated as magnesium hydroxide, which acts as a natural absorbent for silica. These reactions are carried out in a vat or tank that is located just head of the zeolite softener tank. The effluent from this tank is filtered and then introduced into the zeolite softener. There is always some residual hardness leakage from the hot-process softener to be removed in the final zeolite process. The hot lime process operates at about 220°F (104°C). At this temperature the potential for the exchange of sodium for hardness ions is greater than at ambient temperature, and the result is a lower hardness effluent than is achieved at ambient temperatures. This system is shown schematically in Fig. 2.

Hot Lime Zeolite–Split Stream Softening. Many raw waters softened by the first two processes would contain more sodium bicarbonate than is acceptable for boiler feedwater purposes. Sodium bicarbonate will decompose in the boiler water to give caustic soda. Caustic soda in high concentrations is corrosive and promotes foaming. The American Boiler Manufacturers Association has adopted the standard that the alkalinity content should not exceed 20% of the total solids of the boiler water. Split stream softening provides a means for reducing the alkalinity content.

This requires a second zeolite tank that has a zeolite resin in the hydrogen form in addition to the usual tank with the resin in the sodium form. The two tanks are operated in parallel. In one tank, calcium and magnesium ions are replaced by hydrogen ions. The effluent from this tank with the resin in hydrogen form is on the acid side and has a lower total-solids content. The total flow can be proportioned between the two tanks to produce an effluent with any desired alkalinity as well as excellent hardness removal. When the hydrogen resin is exhausted, it is regenerated with acid.

Demineralization and Evaporation. At drum pressures over 1000 psi (68 atm), demineralization or evaporation of the makeup water is generally desirable. A water that closely approaches theoretical chemical purity can be obtained by either of these processes.

Evaporation as a source of purified water does not involve ion exchange. It is actually a distillation process, consisting of evaporation, leaving most of the solids behind, and recondensation of the purified water. While evaporated water is quite satisfactory, economics generally favors demineralization.

Demineralization, like the zeolite process, involves ion exchange. The metal ions are replaced with hydrogen ions by means of the process and equipment described for the hydrogen-zeolite system (see **Hot Lime Zeolite—Split Stream Softening**, previously described). In addition, the salt anions (bicarbonate, carbonate, sulfate and chloride) are replaced by hydroxide ions by means of a specially prepared resin saturated with hydroxide ions.

The two types of resins can be located in separate tanks. In this system, the two tanks are operated in series in a cation-anion sequence. The anion resin is regenerated after exhaustion with a solution of sodium hydroxide. The cation resin is regenerated with an acid, either hydrochloric or sulfuric. Some leakage of cations always occurs in a cation exchanger, resulting in leakage of alkalinity from the anion exchanger.

In another arrangement, known as the mixed-bed demineralizer, the two types of resins are mixed together in a single tank. In the mixed-bed demineralizer, cation and anion exchanges take place virtually simultaneously, resulting in a single irreversible reaction that goes to completion. Regeneration is possible in a mixed bed because the two resins can be hydraulically separated into distinct beds. The cation resin is approximately twice as dense as the anion resin. Resins can be regenerated in place or sluiced to external tanks for this purpose.

The raw water for drum-type boilers operating above 2000 psi (136 atm) drum pressure and for once-through units should be prepared by passing water through a mixed-bed demineralizer as a final step before adding to the cycle.

The effluent from demineralization is approximately neutral. With nearly all salts removed, the problem of chemical control of the boiler water is minimized.

Treatment of Condensate

In most cases, condensate does not require treatment prior to reuse. Makeup water is added directly to the condensate to form boiler feedwater. In some cases, however, especially where steam is used in industrial processes, the steam condensate is contaminated by corrosion products or by the in-leakage of cooling water or substances used in the process. Hence steps must be taken to reduce corrosion or to remove the undesirable substances before the condensate is recycled to the boiler as feedwater.

The presence of acidic gases in steam makes the condensate acidic with consequent corrosion of metal surfaces. In such cases, the corrosion rate can be reduced by feeding to the boiler water chemicals that produce alkaline gases in the steam. The addition of neutralizing and filming amines to boiler water or to condensate to minimize corrosion by condensate and feedwater is discussed later under *Control of* pH.

Many types of contaminants can be introduced to condensate by various industrial processes. They include liquids, such as oil and hydrocarbons, as well as all sorts of dissolved and suspended materials. Each installation must be studied for potential sources of contamination. The recommendations of a water consultant should be obtained to assist in determining corrective treatment.

Fig. 3 shows a condensate purification system used in a paper-mill boiler cycle. The resin beds not only remove dissolved impurities by ion exchange but also serve as filters to remove suspended solids. It is necessary to backwash and regenerate these resin beds periodically. Several types of condensate purification systems are available from various vendors. Some of these are capable of operation at temperatures as high as 300°F (149°C).

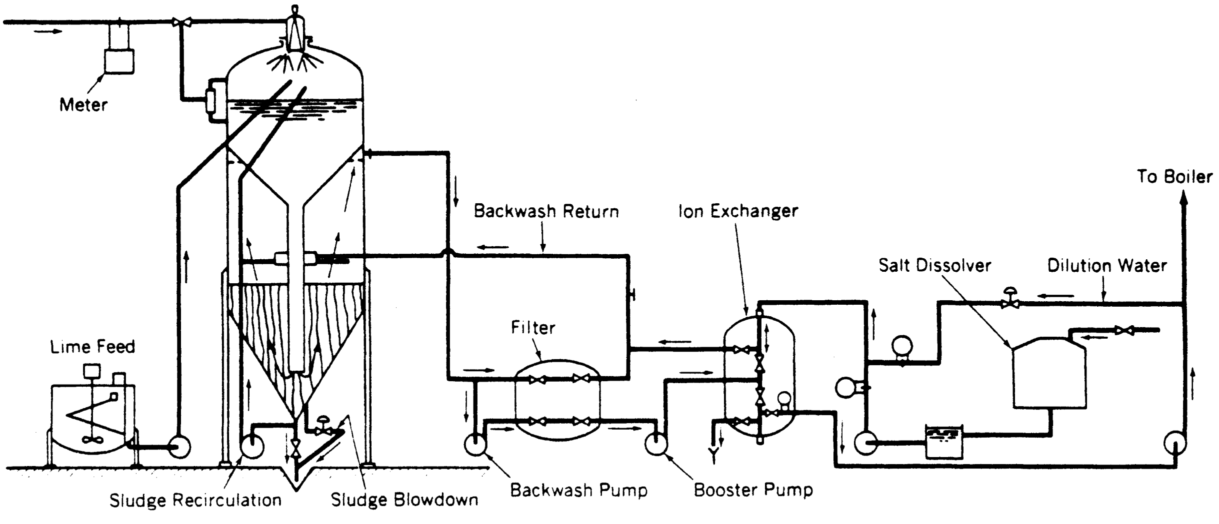

Fig. 2. Flow sheet of typical hot lime zeolite softening process. (*Betz "Handbook of Industrial Water Conditioning."*)

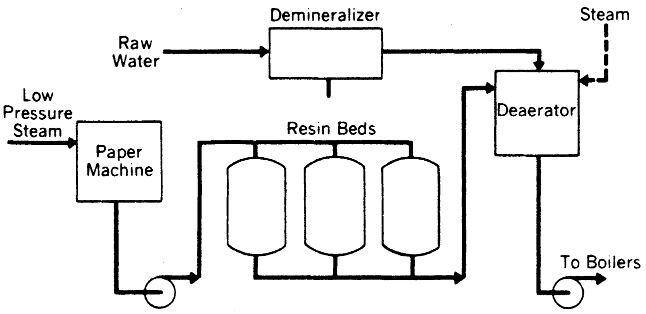

Fig. 3. Condensate purification system. (*Cochrane Div., Crane Company.*)

One such example of a condensate purification system is the use of ion exchange equipment as shown in Fig. 3 for a typical paper-mill boiler cycle. The resin beds not only remove dissolved impurities by ion exchange, but also serve as filters to remove suspended solids, such as products of corrosion. It is necessary to backwash and regenerate such resin beds periodically. These resin beds can be purchased for in-place regeneration or for regeneration in external tanks. External regeneration facilitates more efficient removal of suspended metal oxides from resin beds.

Where significant quantities of magnetic oxide or other magnetic species are present in the condensate-feedwater system, the application of an electro-magnetic filter (EMF) to effectively remove these suspended solids has been proved to be quite successful in both operation and performance. The EMF, Fig. 4, consists of a pressure vessel, coil, spheres, and a power control unit. The pressure vessel is constructed of a non-magnetic material and contains a featherbed of magnetizable spheres of approximately $\frac{1}{4}$-in. (6.5-mm) diam. The pressure vessel is surrounded by a magnetic coil which is supplied with direct current from the power control unit. Flow is upward through the filter both during operation and when flushing the filter, thereby minimizing and simplifying the piping and valving system. Some other advantages that the electro-magnetic filter offers are low pressure drop through the filter, minimum quantity of flush water, entire backwash process only takes several minutes and no chemicals are required in its use.

Laboratory analysis of flush water indicates that some non-magnetic iron oxide may also be retained by the EMF. The non-magnetic iron removal is believed to be due to the presence of magnetic/non-magnetic composite particles, which are magnetically attracted by the filter.

Condensate-Polishing Systems. Demineralizer systems, installed for the purpose of purifying condensate, are known as condensate-polishing systems. A condensate-polishing system is a requisite to maintain the purity required for satisfactory operation of once-through boilers (see **Water Treatment (Boiler)**). High-pressure drum-type boilers (over 2000 psi; 136 atm) can and do operate satisfactorily without condensate polishing. However, many utilities recognize the benefits of condensate polishing in high-pressure plants, including:

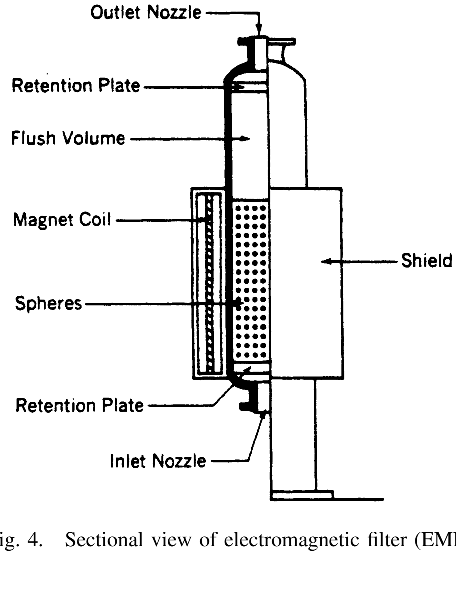

Fig. 4. Sectional view of electromagnetic filter (EMF).

1. Improved turbine capability and efficiency.
2. Shorter unit start-up time.
3. Protection from the effects of condenser leakage.
4. Longer intervals between acid cleanings.

Two types of condensate-polishing systems are available, both capable of removing suspended material, such as corrosion products, as well as ionized solids.

Deep-bed demineralizers operate at flow rates of 40–60 gpm per sq ft (1624–2441 liters/minute/square meter) of bed cross section. This type requires external regeneration facilities. The deep-bed system has a higher initial cost with possible lower operating costs, especially during initial unit start-up. Its greater capacity for removing ionized solids permits continued operation with small amounts of condenser leakage. The deep-bed system is usually operated with the cation resin in the hydrogen form, but the ammonium form can also be used. The cost of regenerating the resin in the ammonium form is greater than for the hydrogen form, but the time period between regenerations is much longer.

The cartridge-tubular type, such as the Powdex system, uses smaller amounts of disposable resins, eliminating the need for regeneration. The Powdex system uses cation resin in the ammonium form. Because of the many considerations involved, an evaluation of alternate types should be made before a system is selected for any given installation.

Use of the EMF with ion exchange equipment in a condensate purification system provides the ultimate in condensate polishing. Location of the EMF upstream of the resin beds offers the advantages of longer operating periods for the beds, thereby reducing the frequency of bed regeneration, and, subsequently, lesser costs for regeneration chemicals.

Treatment of Feedwater

The following discussion outlines what is required to produce and maintain the quality of feedwater recommended in Table 1.

The pre-boiler equipment, consisting of feedwater heaters, feed pumps and feed lines, is constructed of a variety of materials, including copper, copper alloys, carbon steel, and phosphor bronzes. To reduce corrosion, the makeup and condensate must be at the proper pH level and free of gases such as carbon dioxide and oxygen. The optimum pH level is that which introduces the least amount of iron and copper corrosion products into the boiler cycle. This optimum pH level should be established for each installation. It generally ranges between 8.0 and 9.5

Control of pH. The control of corrosion in the condensate system is generally accomplished by adding one of the following chemicals:

1. Neutralizing amines—ammonia, morpholine, cyclohexylamine and hydrazine.
2. Filming amines—octadecylamine acetate.

Neutralizing amines are volatile alkalizers that distill with the steam and neutralize acids that form in the condensate. Hydrazine, which is also an excellent oxygen scavenger, is included with the volatile alkalizers. It decomposes in the boiler, forming ammonia, hydrogen and nitrogen. The ammonia provides pH control in the condensate. The use of hydrazine as an oxygen scavenger is discussed later under *Chemical Scavenging of Oxygen by Hydrazine*.

Selection of the proper alkalizer should be considered for each plant to minimize the pickup of iron and copper in the condensate and feedwater. Optimum conditions should be established by tests during the early

TABLE 1. RECOMMENDED LIMITS OF SOLIDS IN BOILER FEEDWATER

Drum pressure	Below 600 psi (41 atm)	600 to 1,000 psi (41–68 atm)	1,000 to 2,000 psi (68–136 atm)	Over 2,000 psi (136 atm)
Total solids, ppm			0.15	0.05
Total hardness (as ppm $CaCO_3$)	0	0	0	0
Iron, ppm	0.1	0.05	0.01	0.01
Copper, ppm	0.05	0.03	0.005	0.002
Oxygen, ppm	0.007	0.007	0.007	0.007
pH	8.0–9.5	8.0–9.5	8.5–9.5	8.5–9.5
Organic	0	0	0	0

operation of the unit. Factors to be considered in selecting the alkalizer are steam temperature, makeup requirements, and carbon-dioxide concentration in the condensate.

Condensate corrosion rates are increased by the partial pressure of carbon dioxide in the steam. Carbon dioxide originates in the breakdown of carbonates in the boiler water. If steam has a high carbon-dioxide content, filming amines should be considered as a corrective. Filming amines reduce corrosion rates by forming a protective coating on the surfaces contacted by the steam and condensate. Since this is a surface phenomenon, the amount of metal surface to be protected is more important economically than the concentration of gas in the steam. Control of filming amine feed rate is critical. The protective film will not form if the feed is insufficient while excessive feed of this waxlike substance can plug the flow passages of the equipment.

In units with a high percentage of makeup feed, it may not be necessary to add chemicals specifically for pH control. When the makeup is treated by the lime-soda process or a lime-soda-zeolite system, the effluent is normally within the recommended pH range or slightly higher. If pH exceeds the recommended limits, the high alkalinity may lead to foaming and carry-over. For corrective action, see **Hot Lime Zeolite—Split Stream Softening**, previously discussed.

Control of Oxygen. The presence of gases, particularly oxygen, leads to corrosion of the boiler and cycle equipment. This type of attack will occur in an operating boiler as well as an improperly stored idle boiler. The consequent effect of dissolved oxygen in feedwater is pitting of the internal surfaces. This is most prevalent in the economizer, the steam drum and the supply tubes. The pitting may be general or selective. In either case, if allowed to proceed unchecked, it will adversely affect the reliability of the unit and shorten its service life.

The most logical approach to the prevention of corrosion by gases is to expel them from the system at the first opportunity. The usual method is by means of a deaerating heater. This equipment must be kept in prime operating order over the complete load range. If the deaerator operates under vacuum at low loads, the entrance of air must be prevented. Oxygen concentrations at the deaerator outlet should be consistently less than 0.007 ppm. As a further assurance against the destructive effect of dissolved oxygen, a residual quantity of an oxygen-scavenging compound should be maintained in the system.

Chemical scavenging of oxygen by sodium sulfite. Most operators use sodium sulfite for the chemical scavenging of oxygen. Fig. 5 shows the recommended sulfite concentration as a function of boiler pressure. The amount of sulfite that can be safely carried decreases as pressure increases. At the high temperatures associated with the higher pressures, sulfite decomposes into acidic gases that can cause increased corrosion. Consequently, sulfite should not be used at pressures greater than 1800 psi. On boilers having spray attemperation, the sodium sulfite should be added after the attemperator take-off point. About 8 ppm is required to remove 1 ppm of oxygen.

Chemical scavenging of oxygen by hydrazine. Hydrazine is an alternate scavenger, offering two principal advantages:

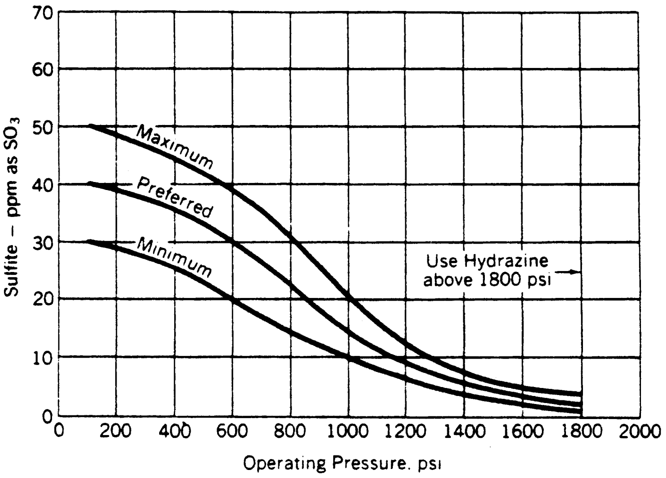

Fig. 5. Usually recommended sulfite residual in boiler water

1. The decomposition and dissolved-oxygen reaction products of hydrazine are volatile. Consequently, they do not increase the dissolved-solids content of the boiler water, nor do they cause corrosion where steam is condensed.
2. Experience has shown that condensate pH will usually stabilize in the range of 8.5–9.5 if a 0.06-ppm hydrazine residual is maintained at the boiler inlet. This eliminates the need for pH treatment of the condensate-feedwater.

It is apparent that a residual of 0.06 ppm of hydrazine will provide only a limited protection against oxygen entering the boiler. Thus it is not practicable to utilize this scavenger as a substitute for an airtight system.

Changes in Feedwater Treatment. Any changes in feedwater treatment or boiler water conditions can have troublesome results. Changes should therefore be made gradually and with close observation. For instance, if sulfite treatment is to be replaced by hydrazine, initial dosage should be small and changes in the iron and copper concentration in the feedwater should be carefully monitored. If iron and copper concentrations in the feedwater and boiler water increase significantly, load should be reduced and blowdown increased. It may require days or weeks for conditions to stabilize, so results must be observed and evaluated over a significant period.

Treatment of Boiler Water for Natural-Circulation Units

Direct treatment of boiler water, usually referred to as internal treatment, is used (1) to prevent scale formations caused by hardness constituents, and (2) to provide pH control to prevent corrosion. Treatment that is incorrect or inadequate in either respect can lead to tube failures and result in costly unscheduled outages. The permissible limits on contaminants entering the boiler and also on treatment chemicals that can be added to the boiler decrease with rising boiler pressures.

Fig. 6 shows the relationship between dissolved solids in boiler water and solids in steam at various drum operating pressures. This correlation agrees reasonably well with both laboratory and field data. If a boiler-water total-solids concentration of 15 ppm is assumed, Fig. 6 indicates that 15 ppb solids would be expected in the steam at 2400 psi (163 atm) drum pressure, while at 2800 psi (190 atm) drum pressure about 75 ppb would be expected in the steam. Fig. 7 indicates the great reduction in silica concentration in boiler water that must occur as pressures increase if silica in the steam is to be limited to 20 ppb. Experience has demonstrated that a concentration of 20 ppb will pass through the superheater and turbine without deposition. This curve is valid for a boiler water pH of 9.5. At the higher pressures, boiler water additives must be reduced to low levels in order to avoid deposits on turbine parts.

There are four methods of internal treatment in common use on natural-circulation drum-type boilers:

1. Phosphate-hydroxide (conventional-treatment).
2. Coordinated phosphate.
3. Chelant.
4. Volatile.

The method of treatment is generally dictated by the pressure range of the unit.

Methods 1 and 2 are intended to control the boiler water pH and to precipitate the calcium and magnesium compounds as a flocculent sludge, so that they can be removed in the boiler blowdown rather than being deposited on heat-transfer surfaces. Method 1 maintains an excess of hydroxide alkalinity. The effects of alkalinity are discussed later under *Steam Purity*. Method 3 involves the addition of a complex metal-chelant compound such as ethylenediamine-tetraacetic acid (Na_4EDTA) or nitrilotriacetic acid (NTA). In Method 4, as the name implies, no solid chemicals are added to the boiler or pre-boiler cycle. The pH of the boiler water and condensate cycle is controlled by adding a volatile amine.

In Methods 1 through 3, either sulfite (up to 1800 psi; 122 atm) or hydrazine can be used as the oxygen scavenger. Above 1800 psi (122 atm), or with the volatile treatment (Method 4), hydrazine is used.

Phosphate-Hydroxide (Conventional-Treatment) Method. This is the most prevalent method of treatment for industrial boilers operating below 1000 psi (68 atm). It involves the addition of phosphate and caustic to the boiler water. Caustic is added in sufficient quantity to maintain a pH of

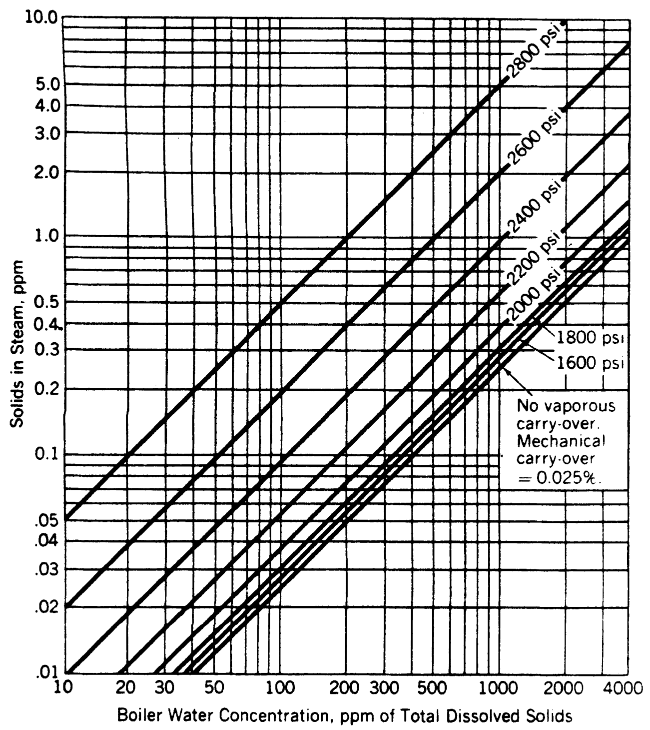

Fig. 6. Solids in steam versus dissolved solids in boiler water

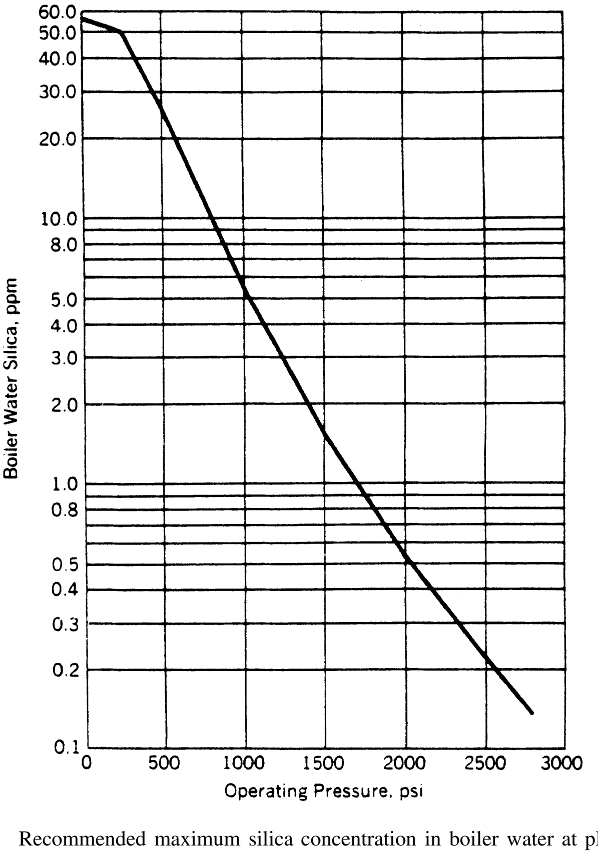

Fig. 7. Recommended maximum silica concentration in boiler water at pH 9.5 (drum-type boilers)

10.5 to 11.2. A boiler treated with caustic and phosphate is less sensitive to upsets than with other methods of feedwater control.

The primary purpose of phosphate addition is to precipitate the hardness constituents. The calcium reacts with phosphate under the proper pH conditions to precipitate calcium phosphate as calcium hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$. This is a flocculent precipitate that tends to be less adherent to boiler surfaces than simple tricalcium phosphate, which is precipitated below 10.2 pH. Caustic reacts with magnesium to form magnesium hydroxide or brucite, $Mg(OH)_2$. This precipitate is formed in preference to magnesium phosphate at a pH above 10.5 as it is less adherent.

The recommended phosphate concentration for a given boiler operating pressure is shown in Fig. 8. At the higher pressures, comparatively low phosphate residuals must be maintained in order to avoid appreciable phosphate "hideout." Hideout is the term used to identify the phenomenon of the temporary disappearance of phosphate in the boiler water upon increase in load and its reappearance upon load reduction. The recommended alkalinity as a function of pressure is given in Fig. 9.

Phosphate hideout does not appear to be as important below 1500 psi (102 atm) and even at this pressure, phosphate concentrations of 12 to 25 ppm as PO_4 can be carried without appreciable hideout. Either sulfite or hydrazine may be used to scavenge oxygen.

Coordinated Phosphate Method. In this method of treatment, no free caustic is maintained in the boiler water. Fig. 10 shows the phosphate concentration versus the resulting pH when trisodium phosphate is dissolved in water. Recent laboratory tests show that the crystals which precipitate from a concentrated solution of trisodium phosphate at elevated temperatures contain disodium phosphate and that the supernatant liquid is rich in sodium hydroxide. The sodium hydroxide can destroy the magnetite protective film on boiler surfaces. To assure that no free caustic is present, a boiler-water phosphate concentration that corresponds to a sodium-to-phosphate mole-ratio of 2.6 is recommended above 1000 psi (68 atm), as

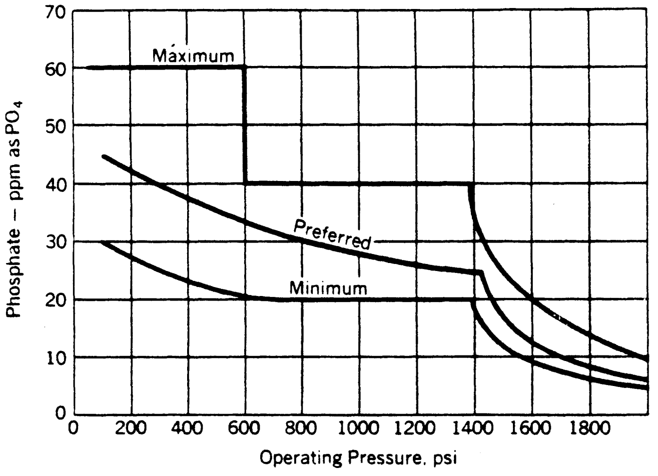

Fig. 8. Recommended phosphate concentration in boiler water at various boiler operating pressures (phosphate-hydroxide treatment)

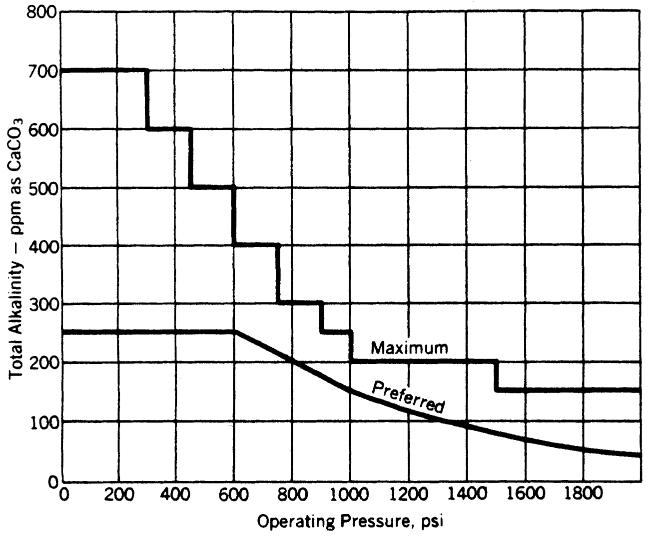

Fig. 9. Recommended alkalinity of boiler water at various boiler operating pressures (phosphate-hydroxide treatment)

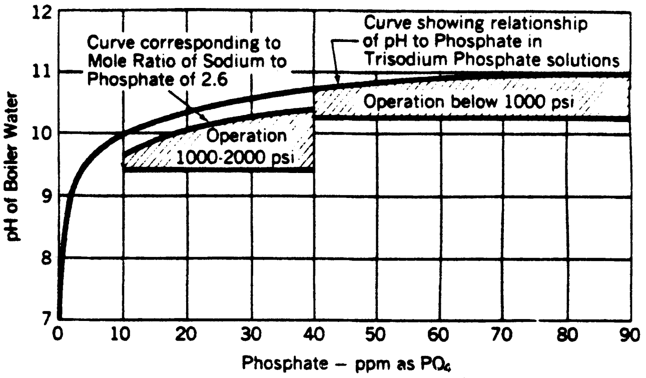

Fig. 10. Recommended phosphate content of boiler water for drum boilers, using coordinated phosphate treatment

shown in Fig. 10. The precaution against free hydroxide alkalinity is less critical in boilers operating below 1000 psi (68 atm). The shaded areas on Fig. 10 indicate the recommended operating range of PO_4 and the resulting pH for boiler pressures to 2000 psi (136 atm). For drum pressures from 2000 to 2835 psi (136–192 atm) the boiler water should contain from 3 to 10 ppm Na_3PO_4 with corresponding pH of 9.0 to 9.7.

When using the regular commercial grades of chemicals, caution should be used in calculating the weights needed to provide the proper mole ratios. Commercial phosphates commonly are in the form of $Na_3PO_4 \cdot 12H_2O$ and $Na_2HPO_4 \cdot 7H_2O$. A mixture of 65% $Na_3PO_4 \cdot 12H_2O$ and 35% $Na_2HPO_4 \cdot 7H_2O$ corresponds to a mole ratio of Na to PO_4 of 2.6. If the pH is too low, it may be corrected by increasing the ratio of trisodium to disodium phosphate. If the pH is too high, the ratio should be decreased.

Use of Chelants. This method of water treatment has become popular in recent years with industrial boiler operators. These organic agents react with the residual divalent metal ions, calcium, magnesium and iron, in the feedwater to form soluble complexes. The resultant soluble complexes are removed through continuous blowdown. This method of treatment has been used in boilers operating as high as 1500 psi (102 atm) although present B&W recommendations limit its use to units below 1000 psi (68 atm).

Certain precautions are necessary in using this treatment. The chelating agents do not chelate ferric iron or copper. The presence of chelating agents and oxygen together, in the boiler or pre-boiler cycle, must be avoided. During operation, deaeration must be good at all times, and measures must be taken to protect the boiler from oxygen at all times during off-line periods.

Experience indicates that it is difficult to control chelant feed based on chelant residual in the boiler water. Excess chelant will attack clean boiler surfaces. B&W therefore recommends that chelant feed be based on known quantities of hardness and iron present in the feedwater, with the objective of maintaining a residual approximating 1 ppm of chelant in the boiler water. To protect the boiler from upsets resulting from heat-exchanger leakage or makeup plant overrun, a phosphate residual of 15 to 30 ppm should be maintained in the boiler water. The boiler internal surfaces should be inspected whenever opportunity permits. If sludge deposits accumulate, the chelant feed should be increased by 1 to 2 ppm. If the boiler is found to be exceptionally clean and shiny surfaces are in evidence, the chelant feed should be decreased. A light gray dust on the internal boiler surfaces appears to characterize the ideal condition.

For handling chelants, chemical feed piping must be made of stainless steel or some other corrosion-resistant material.

Volatile Treatment. This method of treatment may be used for units operating above 2000 psi (136 atm) drum pressure. In this method, no solid chemicals are added to either the boiler or pre-boiler cycle. By eliminating solid treatment, the volatile carry-over of solids is eliminated and consequently turbine deposits are avoided. Cycle pH is controlled at 9.0 to 9.5 with a volatile amine such as ammonia. Hydrazine is added as an oxygen scavenger in quantity sufficient to provide a concentration of 20 to 30 ppb at the economizer inlet.

With volatile treatment, the feedwater must not contain hardness of condenser-leak constituents. Since no phosphate is present to remove hardness, any contamination assumes major importance. Prompt detection and remedial action is required. Failure to take such action endangers the future availability of the unit. A condensate-polishing system in the cycle is the best insurance against condenser leakage and hardness constituents.

Steam Purity. The trend toward higher pressures and temperatures in steam power plant practice imposes a severe demand on steam-purification equipment for elimination of troublesome solids in the steam. Carry-over may result from ineffective mechanical separation and from the vaporization of boiler-water salts. Total carry-over is the sum of the mechanical and vaporous carry-over of all impurities.

Mechanical carry-over is the entrainment of small droplets of boiler water in the separated steam. Since entrained boiler-water droplets contain solids in the same concentration and proportions as the boiler water, the amount of impurities in steam contributed by mechanical carry-over is the sum of all impurities in the boiler water multiplied by the moisture content of the steam. Foaming of the boiler water results in gross mechanical carry-over. The common causes of foaming are excessive boiler-water solids, excessive alkalinity or the presence of certain forms of organic matter, such as oil.

Maintaining dissolved solids at the level required to prevent foaming requires continuous or periodic blowdown of the boiler. Table 2 gives the recommended total solids concentration for the prevention of excessive carryover at various operating pressures. Most operators find it convenient and advisable to run well below these limits. Exceeding them may endanger the superheater, the turbine, or the process application.

High boiler-water alkalinity tends to increase carryover, particularly in the presence of an appreciable quantity of suspended matter. This effect may be corrected by various methods, dependent on the cause of the high alkalinity. For example, if trisodium phosphate is being added to the boiler water, a less alkaline phosphate, such as disodium or monosodium phosphate will help in reducing alkalinity.

The presence of oil in boiler water is intolerable, as it causes foaming and carry-over. Steps should be taken to prevent its entry into the boiler through the feedwater system or leakage through pressure seals and joints. Organic antifoaming agents are a recent development with some successful application. However, their use should not be considered a cure-all.

Spray water for use in a spray attemperator should be of the highest quality. Solids entrained in the spray water enter the steam and can cause troublesome deposits on superheater tubes and turbine blades.

Carry-over of volatile silica is generally a problem only at pressures of 1000 psi (68 atm) or above, although it can be encountered at pressures as low as 600 psi (41 atm). For the protection of the turbine, it is important that silica carryover be prevented in this pressure range by adherence to the silica limits of Fig. 7.

The prevention of vaporous carry-over is much more difficult than the correction of mechanical carry-over. The only effective method is to reduce the solids concentration in the boiler water.

Controls for Water Conditioning

The safe and efficient operation of boilers at pressures over 1000 psi (68 atm) requires continuous monitoring of the water conditioning system. Early detection of any contamination entering the system is essential, so that immediate corrective action can be taken before the boiler and its related equipment are damaged.

Electrical conductance, the reciprocal of resistance, affords a rapid means of checking for contamination in a water sample. Electrical conductance of a water sample is the measure of its ability to conduct an electric current. It can be related to the ionizable dissolved solids in the

TABLE 2. LIMITS FOR TOTAL SOLIDS CONTENT IN BOILER WATER (DRUM BOILERS)

Drum pressure		Total solids
(psi)	(atm)	(ppm)
0–300	0–20.4	3500
301–450	20.5–30.6	3000
451–600	30.7–40.8	2500
601–750	40.9–51.0	2000
751–900	51.1–61.2	1500
901–1000	61.3–68.0	1250
1001–1500	68.1–102.0	1000
1501–2000	102.1–136.1	750
over 2000	over 136.1	15

water. A single instrument will measure and record important conductivities of the water from as many as twenty different locations in the system. The electrical conductivity signal can be used to actuate alarm systems or to operate equipment in the water system. The micromho (1×10^{-6}mho) is normally the unit of measurement. For most salts in low concentrations, 2 micromhos is equal to 1 ppm concentration when corrected to 77°F (25°C).

Ammonia or amines used for pH control affect the conductivity. To obtain an accurate indication of solids, a cation ion exchanger removes the volatile alkalizers and converts the salts to their corresponding acids. Seven micromhos are equivalent to 1 ppm concentration for most salts.

For boilers with operating pressures over 1000 psi (68 atm) cation conductivity of the condensate should normally run between 0.2 and 0.5 micromhos. A reading above this limit indicates the presence of condenser leakage or contamination from some other source. The source of the contamination should be investigated and remedied at the first opportunity. However, when a cation conductivity limit of 1.0 is reached, the internal water treatment and blowdown must be changed appropriately.

Dissolved oxygen should be monitored at the condensate pump discharge and the deaerator outlet. Sulfite or hydrazine can be used for oxygen scavenging. Over 1800 psi (122 atm) drum pressure, sulfite should not be used; only hydrazine is recommended. Sulfite or hydrazine can be added to the condensate on a manual or automated basis.

Feedwater pH is monitored at the condensate pump discharge and the economizer inlet. Chemical-injection pumps are usually adjusted manually to maintain the proper pH for the conventional and coordinated phosphate water-treatment systems. Where volatile water treatment is used, pH can be controlled automatically by using conductivity to transmit signals to the ammonia injection pumps. It is generally preferable to use conductivity rather than pH to transmit signals to the ammonia pumps. Conductivity equipment has been found to be more reliable for this purpose and the linear, rather than logarithmic relationship to concentration, enables better control. Ammonia should be added at the hotwell effluent, or, if condensate polishing is used, at the effluent of the demineralizing system.

Hydrogen should be monitored at the economizer inlet and the superheater outlet. A hydrogen analyzer-recorder can actuate an alarm when the hydrogen concentration of the feedwater or steam deviates from the safe value, which is specified for the plant. Deviation from the normal hydrogen concentration can indicate that corrosion is taking place within the water-steam system.

Automated equipment is commercially available for the continuous on-stream analysis of the critical constituents of the boiler water, such as hardness, phosphate, iron, copper and silica. Most laboratory analytical procedures that depend on the development of a color, and then measuring the intensity of that color to indicate the concentration of the constituent in the water sample, can be put on an automatic basis.

Water Treatment for Universal-Pressure Boilers

Satisfactory operation of the once-through boiler and associated turbine requires that the total solids in the feedwater be less than 0.05 ppm. Table 3 lists recommended maximum limits for feedwater contaminants and typical values obtained during operation.

Recommended limits should be low because all solids in the feedwater will either deposit in the boiler or be carried over with the steam to the turbine. Consequently, water-treatment chemicals must be volatile. All cycles should have condensate-polishing systems to meet the limits shown in Table 3. A schematic diagram is shown in Fig. 11. Laboratory tests as well as field studies show that high-flow-rate condensate-polishing systems [25 to 50 gal per min per sq ft (1015–2030 liters/minute/square meter) of cross-sectional bed area] perform as filters of suspended material and ionized particles. Ammonia is added to control the pH in the system. Fig. 12 indicates the amount of ammonia required, in terms of ppm or solution conductivity, to give a certain pH in the system. Hydrazine is added to the cycle for oxygen scavenging.

Most of the iron entering the boiler originates in the condensate-feedwater cycle downstream of the polishing demineralizers or in the shell side of feedwater heaters where drips bypass the polishing demineralizers. Studies on a number of installations with carbon-steel feedwater heaters have shown that iron pickup can be minimized by operating with feedwater pH in the range of 9.3 to 9.5. The best pH for minimizing iron pickup

TABLE 3. RECOMMENDED LIMITS OF SOLIDS IN FEEDWATER FOR UNIVERSAL-PRESSURE BOILERS

	Maximum limit	Typical concentrations
Total solids	0.050 ppm	0.020 ppm
Silica as SiO_2	0.020 ppm	0.002 ppm
Iron as Fe	0.010 ppm	0.003 ppm
Copper as Cu	0.002 ppm	0.001 ppm

Organic	0.0 ppm	0.002 ppm
pH	9.2–9.5	9.45

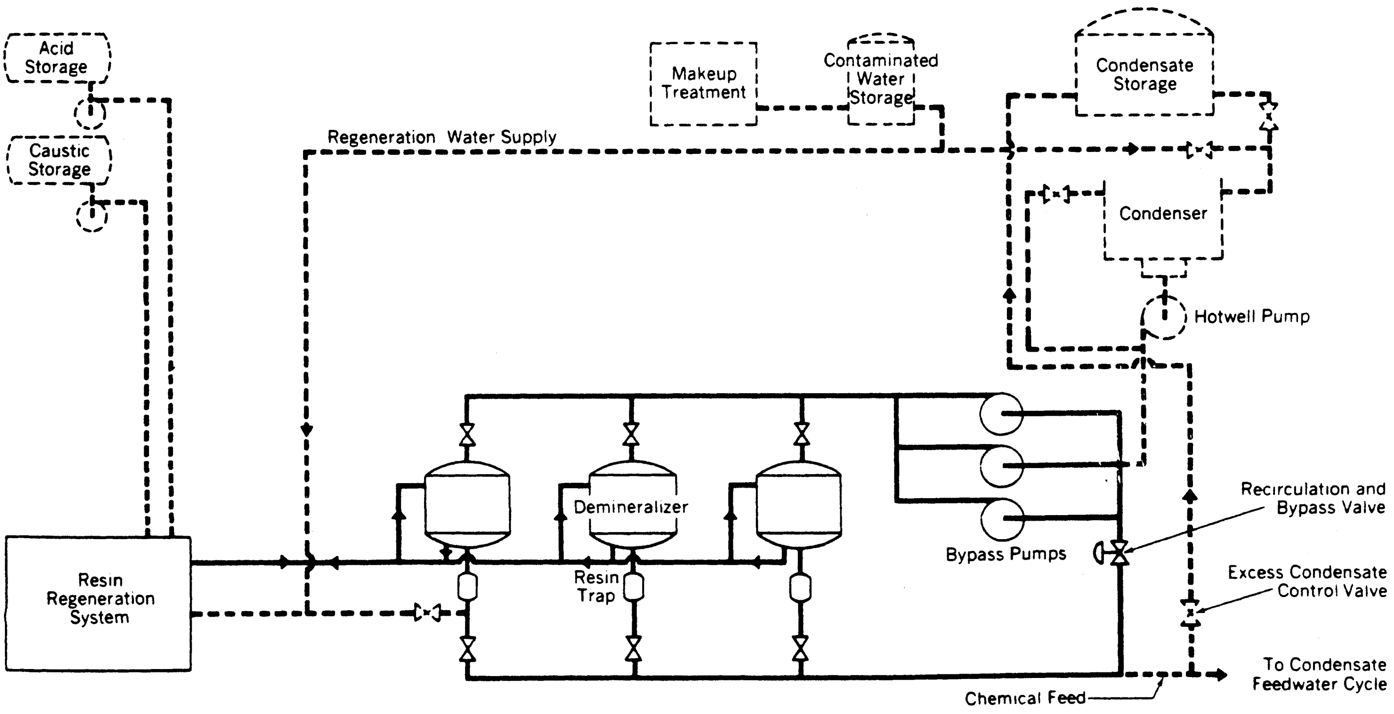

Fig. 11. Schematic diagram of condensate-polishing system with high-quality makeup treatment (four-bed ion exchange or equivalent)

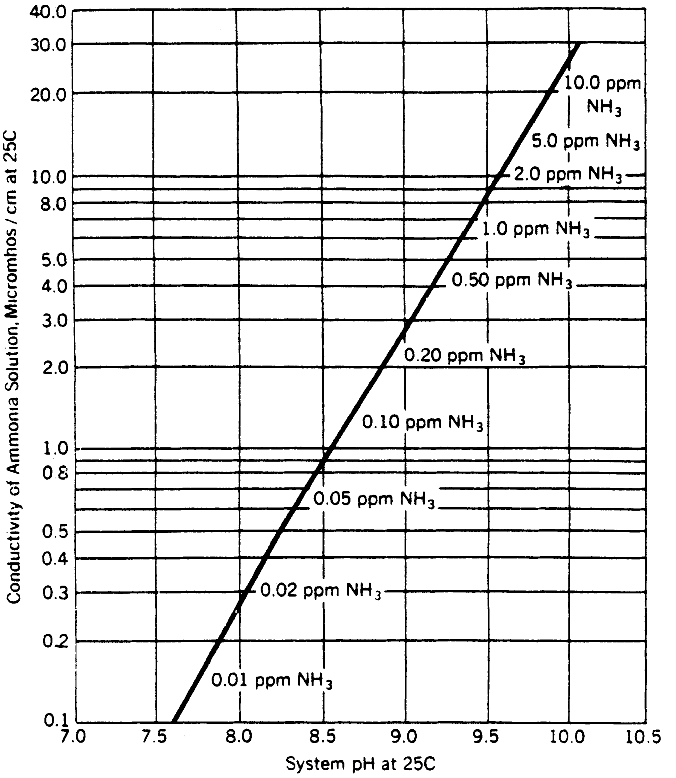

Fig. 12. Theoretical relationship between conductivity and pH for ammonia solutions

should be determined for each cycle during the first several months of operation.

Ammonia is injected downstream of the condensate polishers and controlled from a sample taken far enough downstream of the injection point to assure good mixing. Hydrazine is generally fed at the exit of the condensate-polishing system and/or at the boiler feed-pump suction. Automatic controls are available to regulate the positive displacement pumps that meter ammonia and hydrazine introduction. The signal to the pump-controller for ammonia usually comes from a specific conductivity-recording instrument that is compensated for temperature changes of the cycle water. Hydrazine feed is frequently automatic, utilizing an analyzer and controller. Hydrazine residuals of 10–20 ppb are normally maintained at the boiler inlet.

Prior to plant start-up, either initially or after long outages, water must be circulated through the condensate-polishing system to reduce the dissolved material and suspended particles. The cation conductivity of the cycle water must be reduced to less than 1.0 micromho before a fire is lighted in the unit. Temperatures are not allowed to exceed 550°F(288°C) at the convection pass outlet until the iron levels are less than 100 ppb at the economizer inlet. Cation-conductivity and suspended-iron requirements are generally met after 4 to 5 hours of circulation with cycles having a bypass arrangement.

Many units have instrumentation that will trip the unit in case of excessive feedwater contamination. Trip-limit recommendations are based on the measurement of cation conductivity at the boiler inlet. An actual unit trip is usually preceded by alarms at the hotwell discharge to warn the operator of feedwater contamination and possible load reduction. In setting feedwater trip limits, protection of both the boiler and the turbine must be considered. A common arrangement consists of two cation conductivity alarm devices, both required to read high to initiate the trip sequence. A conductivity of 2 micromhos for five minutes or 5 micromhos for two minutes, results in a unit trip. Properly installed and maintained, these trip devices are highly reliable.

WATSON, JAMES DEWEY (1928–). James Watson, an American chemist, was a brilliant student who began college at the University of Chicago at the young age of 15. Since he was young, Watson had a passion for bird watching and this interest was probably a factor in his fascination with genetics. He is known for his research contributions in the field of genetics.

He began working with Francis Crick in 1950 at the Cavendish laboratories. In 1953, Watson and Crick, using the photographs of Rosalind Franklin, which exposed crystallized molecules from the nucleus, identified the material that biologists were viewing in the nucleus as DNA. Watson and Crick created a three-dimensional structure DNA model, which provided scientists with a valuable tool in the study of heredity. In 1962 Watson-Crick were awarded the Nobel Prize for their work.

Watson taught at Harvard and CalTech and in 1968 he became the directorship for Cold Spring Harbor Laboratory. Under his directorship the lab became a leading research center in the world for molecular biology. In 1988, Watson became head of the Human Genome Project.

J.M.I.

WAVELLITE. The mineral wavellite is a hydrous phosphate of aluminum, formula $Al_3(PO_4)_2(OH)_3 \cdot 5H_2O$. It is orthorhombic but crystals are of rare occurrence as it is ordinarily found in crusts or radial aggregates, sometimes fibrous. Its hardness is 3.25–4; specific gravity, 2.36; may be of various colors, gray, blue, green, yellow, black, or colorless. It has a vitreous luster, and is translucent. This mineral is of secondary origin, probably formed by waters bearing phosphoric acid which have acted on aluminum minerals. Wavellite is found in Saxony, Bavaria, Devonshire, from where it was originally described; and in the United States in Chester and Cumberland Counties, Pennsylvania; and Montgomery and Garland Counties, Arkansas. It was named after its discoverer, Dr. Wavel.

WAXES. The English term *wax* is derived from the Anglo-Saxon *weax*, which was the name applied to the natural material gleaned from the honeycomb of the bee. In modern times the term *wax* has taken on a broader significance, as it is generally applied to all waxlike solids, natural or synthetic, and to liquids when they are composed of monohydric alchol esters. Unlike the ordinary oils of animal and vegetable origin and the animal tallows, the waxes, with a few exceptions, are free from glycerides, which are common constituents of oils and fats. Bayberry wax is a vegetable tallow which happens to have all the physical characteristics of a wax, and has always been classed as such.

Animal and Vegetable Waxes

The most important insect wax from an economic viewpoint is *beeswax*, secreted by the hive-bee. Wax scales are secreted by eight wax glands on the underside of the abdomen of the worker bee. These wax wafers are used by the bee in building its honeycomb. From $1\frac{1}{2}$ to 3 pounds of wax can be obtained from the combs when they are scraped. The crude wax must be rendered and refined before it can be sold as "yellow beeswax." When this is bleached, it is known as "white beeswax."

The chemical components of beeswax are alkyl esters of monocarboxylic acids (71–72%), cholesteryl esters (0.6–0.8%), coloring matter (0.3%), lactone (0.6%), free alcohols (1–$1\frac{1}{2}$%), free wax acids (13.5–14.5%), hydrocarbons (10.5–11.5%), moisture and mineral impurities (0.9–2%). Myricyl palmitate ($C_{46}H_{92}O_2$) is the principal constituent of the simple alkyl esters (49–53%); the simple esters include alkyl esters of unsaturated fatty acids. The complex esters include hydroxylated esters the chief component of which is believed to be ceryl hydroxypalmitate, $C_{42}H_{84}O_3$. The principal free wax acid component is cerotic acid ($C_{26}H_{52}O_2$). The principal hydrocarbon is hentriacontane ($C_{31}H_{64}$).

The uses of beeswax are many, including church candles, electrotypers and pattern makers wax, cosmetic creams, adhesive tape, munition shells, modelling of flowers, shoe paste constituent, etc. The United States consumes about 8 million pounds of beeswax annually, more than half of which it imports from foreign countries.

Although there are many other kinds of insect waxes, only two are of economic importance namely, shellac wax and Chinese insect wax. Shellac wax is derived from the lac insect, a parasite that feeds on the sap of the lac tree indigenous to India. The commercial wax is not ordinarily the native Indian lac wax, but is a by-product recovered from the dewaxing of shellac spar varnishes. Lac wax melts at 72–80°C, whereas commercial shellac wax melts at 80–84.5°C. Its high melting point and dielectric properties favor its use in the electrical industry for insulation. Chinese insect wax is the product of the scale insect.

The land animal waxes are either solid or liquid. *Woolwax*, derived from the wool of the sheep, is of great economic value. It is better known as anhydrous lanolin, and is of a stiff, soft, solid consistency. The only representative of liquid animal wax is "mutton bird oil" obtainable from the stomach of the mutton bird.

The unsaponifiables of woolwax, known as "woolwax alcohols," are in considerable demand by cosmetic and pharmaceutical industries. Woolwax has a great affinity for water, of which it will absorb 25 to 30%. Refined woolwax is kneaded with water to produce a water-white, colorless ointment, known as hydrous lanolin or "lanolin USP." Anhydrous lanolin is widely used in cosmetic creams, since it is readily absorbed by the skin. It is also used in leather dressings and shoe pastes, as a superfatting agent for toilet soap, as a protective coating for metals, etc. United States consumption of wool wax is about 1.5 million lb/year.

The marine animal waxes are both solid and liquid. The solid marine animal waxes are represented by a wax of considerable economic importance, namely *spermaceti*, derived from a concrete obtained from the head of the sperm whale. The liquid waxes of marine animals are represented by sperm oil obtained from the blubber and cavities in the head of the sperm whale. Spermaceti is the wax used in the candle which defines our unit of candle power; it is used chiefly as a base for ointments, cerates, etc. Sperm oil contains a considerable amount of esters made up of unsaturated alcohols and acids, both of which are susceptible to hydrogenation. Hydrogenated sperm oil is the equivalent of spermaceti wax and harder than the commercial pressed spermaceti. Both yield cetyl alcohol as the unsaponifiable. There is a fairly large demand for cetyl alcohol in the manufacture of lipstick, shampoo, and other cosmetics. Sperm oil itself is an excellent lubricant for lubricating spindles of cotton and woolen mills, or wherever there is need for a very light, limpid, nongumming lubricant.

The waxes obtained from plants occur in the leaves, stems, barks, fruit, flowers, and roots. The leaves of palm trees furnish wax of great economic importance. Particularly is this true of the product furnished by harvesting the leaves of the carnauba palm. The wax is removed from the leaves by sundrying, trenching, threshing and beating; the powdered wax is melted in a clay or iron pot over a fire, strained, cast into blocks, and broken into chunks for shipment from Brazil. *Carnauba wax* dissolves well in hot turpentine and/or naphtha, from which solvents it gels or cooling; it has a good solvent retention power. Its hardness, luster, and favorable behavior with solvents make it a highly valued ingredient in shoe pastes, floor polishes, carbon paper, etc. A small amount of carnauba, such as 2.5%, when added to paraffin will raise the melting point of the latter enormously (e.g., from 130 to 170°F; 54 to 77°C), making it a very useful ingredient in the production of inexpensive high-melting blended waxes. United States consumption is provided by imports from Brazil which amount to over 11 million lb/year.

The chemical composition of carnauba wax comprises 84–85% of alkyl esters of higher fatty acids. Of these esters only 8–9% (wax basis) are simple esters of normal acids. The other esters are acid esters 8–9%, diesters 19–21%, and esters of hydroxylated acids 50–53% (was basis) of which about one-third are unsaturated. It is the hydroxylated saturated esters that give carnauba its extreme hardness, whereas the esters of the hydroxylated unsaturated fatty acids produce the outstanding luster to polishes.

Ouricury, carandá, and raffia are commercial palm leaf waxes of lesser importance. Ouricury wax has a very high content of esters of hydroxylated carboxylic acids and is used as a substitute for carnauba in carbon papers, etc. Carandá and raffia waxes have a very low contents of these acids and make unsatisfactory substitutes for carnauba.

The most important wax obtainable from the stems of plants is *candelilla*, obtained in Mexico and the southwestern United States. To recover the wax the plant stalks are pulled up by the roots and boiled in acidulated water. On cooling, the congealed wax is removed from the surface of the water in the tank. The crude wax is given an additional refinement before it si placed on the market. Candelilla wax is brownish in color, and melts at 66–78°C. Most vegetable waxes are essentially alkyl esters of aliphatic acids; candelilla, on the other hand, contains 51 to 59% of hydrocarbons and less than 30% of esters. The chief hydrocarbon is hentriacontane ($C_{31}H_{64}$), common to other vegetable waxes. The hydrocarbons melt at 68°C, and the esters at 88–90°C. Candelilla is often used in conjunction with carnauba in leather dressings, floor waxes, etc. It is also used in sound records, electrical insulators, candle compositions, etc. Imports average about 1600 tons per year.

Because of the enormous tonnage of sugar cane processed in Cuba and elsewhere, it is possible to recover an appreciable tonnage of *sugarcane wax* as a by-product. The crude wax contains about one-third each of wax, resin, and oil, and hence needs considerable refinement by selective solvents before it can become of value for industrial use. The refined sugarcane wax is dull yellow in color, melts at 79–81°C and is hard and brittle. It has a durometer hardness of 85–96. It is chemically composed of 78–82% of wax esters, 14% free wax acids, 6–7% free alcohols, and 3–5% hydrocarbons. A proportion of the esters are sterols—sitosterol and stigmasterol—combined with palmitic acid, which are responsible for the good emulsification properties of the wax itself in the preparation of polishes and the like. The proportions of sterols in the refined wax is far less than in the crude wax.

Of waxes obtained from fruits, *japanwax* is the only one of great economic importance, particularly to the Asiatic countries. The wax occurs as a greenish coating on the kernels of the fruit of a small sumac-like tree. Japanwax is actually a vegetable tallow, since it is comprised of 90–91% of glycerides. Peculiarly the glycerides include 3–6.5% (wax basis) of alkyl esters of dicarboxylic acids as well as monocarboxylic acids. The chief dicarboxylic acid is known as japanic acid $[(CH_2)_{19}(COOH)_2]$ which is present with lower as well as higher homologs. The dicarboxylic acids have 19 to 23 carbon atoms, whereas the monocarboxylic acids of the simple glycerides present have 16 to 20 carbons.

The textile industries in the past have been large users of japanwax since it is a source of emulsifying softening agents. Other industries using japanwax include those engaged in the manufacture of rubber, soap, polishes, pomades, leather dressings, cordage, etc. Japanwax is a relatively soft but firm wax, which melts at 48.5–54.5°C. About 3000 tons are normally produced per year in China, and twice that amount in Japan.

Other fruit waxes include *bayberry wax*, used in making Christmas candles since the days of the Pilgrams. The wax of rice bran is coming into commercial use, but waxes of the cranberry, apple, grapefruit, etc. are only of academic interest.

Waxes from grasses include bamboo leaf wax, esparto wax, and hemp fiber wax. Esparto wax is a hard, tough wax with a melting point of 73–78°C, and is the most important grass wax. Most of the esparto wax produced is consumed in the British Isles. It is chiefly useful as a substitute for carnauba. Waxes obtained from roots of various species of plants are minute in quantity and of no economic importance.

Mineral Waxes

The fossil waxes are associated with fossil remains which have not been bituminized, that is, converted to hydrocarbons by geological change. A fossil wax, chemically speaking, is composed largely of saponifiables, such as wax acids and esters. Fossil waxes of nearly pure ester composition are occasionally found in fragments of prehistoric plant life, still in a state of preservation as to the original wax constituents. Not far removed from fossil wax of the pure ester composition is *montan wax*, a natural mineral wax which is essentially an ester wax that has undergone partial bituminization. Montan wax is commercially extracted from the nonasphaltic insoluble pyrobitumen with which it is associated, by means of selective solvents such as alsohol and benzene, or by means of benzene alone. Crude montan wax is black and contains about 30% of resins, which is reduced to 10% or less upon refinement. The chemical components of montan wax (deresinified) are alkyl esters of fatty acids (40%), alkyl esters of hydroxy fatty acids (18%), free wax acids (18%), free monohydric alcohols (3%), resins (<12%), and ketones (<10%). There are a number of industrial uses of montan wax: electrical insulation, leather finishes, polishes, carbon papers, shoe pastes, brewer's pitch, etc. The crude wax is also used as a basic material in the manufacture of many synthetic waxes where its montanic acid content is utilized in making derivatives.

The principal source of the montan wax consumed in the United States is imports in annual amounts of some 3.4 million lb from Germany and Czechoslovakia, where it is derived from lignites and brown coals. Also, one California company extracts it from lignite.

Peat wax has somewhat the same composition as montan wax. It has only been produced on a limited scale in Ireland, where it is processed from the native peat. It has asphaltic constituents that tend to make it incompletely miscible with paraffin waxes.

The earth waxes are naturally occurring mineral waxes consisting of hydrocarbons with some oxygenated resinous bodies which can be eliminated by ordinary refining procedures. The earth wax of great

economic importance is *ozocerite*, which originally was called ceresin wax. Important sources are the Carpathian mountains in Europe and to a far lesser extent Utah. Chemically speaking, ozocerite has hydrocarbons of a type different from those found in paraffin wax, giving it unique physical properties. The melting point of pure Galician ozocerite is 73°C. It is less soluble in organic solvents than paraffin. When added to paraffin wax in amounts of 15% or thereabouts, it will reduce the paraffin crystals to micro size and improve the tensile strength. Crude imported ozocerite has a dielectric constant of 2.37–2.43, the refined 2.03, and domestic (Utahwax) 2.63. Ozocerite is used in the electrical industry, paste polishes, cosmetics, wax flowers, crayons, etc. Of all the waxes it has the greatest affinity for oil.

Petroleum Waxes

Petroleum is the largest single source of hydrocarbon waxes. The largest single use of petroleum waxes is in paper coatings which require about 53% of the total. The second largest use is in candles. The third greatest use in electrical equipment. In contrast, in the early 1950's the largest single use for petroleum waxes was in the manufacture of paper containers for dairy products, and the second was in waxed wrappers for bread. Both outlets are now dominated by plastics.

Crude petroleums differ greatly in both the nature of their hydrocarbons (paraffinic, aromatic, naphthenic, etc.), as well as in their available content of wax. Wax distillates are obtainable with the batch-type, continuous-type, and pipe-still processes, but not from the cracking process. There are, broadly speaking, three principal types of wax encountered in crude oil, namely *paraffin wax, slop wax*, and *petrolatum*. The ordinary procedure in producing slack wax is to pump the paraffin distillate at a temperature of 80–100°F (26.7–38°C) to the paraffin sheds (wax plant), where it is allowed to repose in tanks to promote settling at a temperature between 0 and 32°F (−17.8–0°C). It is then pumped through a bank of cooling units (wax chillers) to hydraulic presses, which squeeze out the wax from the chilled distillate. The product is a soft solid known as *slack wax*. Slack wax finds uses in the industries, but most of it is sweated, pressed, and further refined to produce the various grades of fully refined paraffin wax of commerce. Some of the slack may be "pudged" to the extent that it still contains several percent of oil; it is then called *scale wax*. Most of the scale waxes produced have a melting point (drop) of 126–130°F (52–54°C) (ASTM) and are used in waterproofing thread in the fabrication of cotton duck and canvas, waxing kraft papers, builders' papers, cement bag stock, roofers' felt, car liners, and match splints. Scale wax of very low oil content and higher melting point is used in the manufacture of crayons.

Paraffin wax contains 14 hydrocarbons ranging from $C_{18}H_{38}$ to $C_{32}H_{66}$, solidifying between 27.0 and 68.9°C (80.5 and 156.0°F; 26.9–68.8°C). *Petrolatum wax*, which is a microcrystalline wax, has hydrocarbons ranging from $C_{34}H_{70}$ to $C_{43}H_{88}$, inclusive. Its solidifying range is 71.0–83.8°C (159.7–182.7°F). *Slop wax* (by-product from the heavy distillate in the coking process) has 13 hydrocarbons ranging from C_{26} to C_{43}, solidifying between 55.7 and 83.3°C (132.2 and 182.0°F). *Rod wax* (collected from the sucker rods in the field) has 8 hydrocarbons ranging from C_{35} to C_{41}, solidifying at 73.9 to 82.5°C (165.0–180.5°F).

Fully refined paraffin wax as regularly offered in the market is graded according to its melting point. There are also special refined grades offered by some refining companies, such as the so-called hard block fully refined paraffins with melting points of 138–140°F (58.8–60°C), and 143–145°F (61.6–62.7°C). The tensile strength of a paraffin wax is greatly influenced by the oil content. Ordinarily a well-refined paraffin of 130°F (54°C) melting point will have a tensile strength of about 250 psi (1.7 MPa). The addition of 1 or 2% of an oil-absorbent wax of microcrystalline structure will increase the tensile strength to 350 psi (2.4 MPa).

Microcrystalline Waxes

Microcrystalline petroleum waxes are characterized not only by microcrystalline structure but by very high average molecular weight, manifested by a much higher viscosity than that of paraffin wax. The chlorophyll present in plants is considered to be a microcrystalline wax.

Microcrystalline waxes are obtained as by-products from (a) the dewaxing of "lube oil raffinates," (b) the deoiling of petrolatum produced from deasphaltic residual oil, or (c) the deasphalting and deoiling of settlings of tanks holding crude oil in the oil field. These types of microcrystalline waxes are sometimes referred to as "motor-oil wax," "residual oil microcrystalline wax," and "tank-bottom microcrystalline wax," respectively. They have also been referred to as "micro wax," "petrolatum wax," and "petroleum ceresin," respectively.

The *micro waxes* are graded with 145–150°F (63–66°C) and 160–165°F (71–74°C) ASTM melting points, and are refined by selective solvent extraction from the crude wax, a "mobile slurry." A yield of 25–27% of refined wax of the lower melting point is claimed from S.A.E. 20 motor-oil distillate. These waxes are paraffin-like. *Petrolatum waxes* are of a 145–175°F (63–80°C) melting point range. The *petroleum ceresins* which are refined from deposits taken from tanks near the wells, called lease tanks, or in the refinery storage, have melting points which range between 165 and 195°F (74–91°C). In the solvent dewaxing processes the solvents for effectively separating the microcrystalline waxes vary with the refinery methods and the character of the feed stock.

A microcrystalline wax derived from petroleum may be defined as a solid hydrocarbon mixture, of average molecular weight range of 490 to 800, considerably higher than that of paraffin wax, which is 350 to 420. The viscosity (SUS at 210°F; 99°C) of a microcrystalline wax is within the range of 45 to 120 seconds. The lower limit corresponds to 5.75 and the upper limit to 25.1 centistokes at 210°F (99°C). The penetration value (ASTM) is of wide variation, namely 3 to 33, although sticky oily laminating waxes are encountered with as high a penetration as 60. Microcrystalline waxes have an occluded oil content which is not easily set free as it is in paraffin waxes. Therefore, a microcrystalline wax which has an oil content of 1 to 4% is virtually a dry wax. A microcrystalline wax which shows a penetration 20 to 30, which is desirable for many needs, will have an oil content of 5.5 to 10.5%.

When a microcrystalline wax is added to melted paraffin it acts like a solute with paraffin as the solvent; the melting point of the blend is greatly elevated, and the crystallization of the paraffin is depressed. The behavior is that of a two-phase system until about 15% of the microcrystalline wax has been added. With the addition of 15 percent of the petrolatum wax (M.P. 188°F; 86.6°C) the melting point of the paraffin is elevated from 130 to 160°F (54 to 71°C). For many industrial uses microcrystalline wax is admixed with paraffin wax.

The uses of microcrystalline waxes include adhesives, barrel lining, beater size for paper stocks, beer can lining, carbon papers, cheese coatings, cosmetic creams, drinking cups, electrical insulation, floor wax, fruit coating, glass fabric impregnation, heat sealing compounds, laminants for paper, ordnance packing, paper milk bottles, shoe and leather treatments, vegetable coatings, wax emulsions, wax figures and toys, and other miscellaneous purposes.

Synthetic Waxes

These include the following types:

(1) Long-chain polymers of ethylene with OH or other stop-length groupings at end of chain. An example is polyethylene wax of about 2000 molecular weight.

(2) Long-chain polymers of ethylene oxide combined with a dihydric alcohol, namely polyoxyethylene glycol, ("Carbo-wax").

(3) Chlorinated naphthalenes, ("Halowaxes").

(4) Waxy polyol ether-esters, as for example, polyoxyethylene sorbitol.

(5) Synthetic hydrocarbon waxes prepared by the water-gas synthesis in which carbon monoxide (CO) is reduced by hydrogen (H_2) under pressure, at a predescribed temperature, by means of a catalytic agent. (Fischer-Tropsch waxes "F-T 200" and "F-T 300").

(6) Wax-like ketones, straight-chain and cyclic: (a) Symmetrical ketones produced by the catalytic treatment of the higher fatty acids. (b) Unsymmetrical ketones produced by the Friedel-Crafts' condensation of fatty acids and the like with cyclic hydrocarbons. Examples of the straight-chain ketones are laurone, palmitone, and stearone, and of the cyclic ketones are phenoxyphenyl heptadecyl ketone.

(7) Amide derivatives of fatty acids. The length of the chain may be increased by heating the fatty acid, e.g., stearic acid, with an amino alcohol.

(8) Imide (N) condensation products that are wax-like are those of the condensation reaction of one mole of phthalic anhydride with one mole of a primary aliphatic amine to produce a phthalimide. Phthalimide waxes are used in polishes and carbon paper.

(9) Polyoxyethylene fatty acid esters are produced by the reaction of polyethylene glycols with fatty acids. The commercial products are waxy solids which include "Carbowax 4000 (Mono) Stearate." Some of the products act as plasticizers and lubricants for plastics. The polyethylene glycols are soluble in water.

(10) Miscellaneous synthetic waxes (unclassified).

In addition to the above waxes there is a group of synthetic wax-like emulsifiable materials extensively employed in the industries. They are the polyhydric alcohol fatty acid esters, such as ethylene glycol monostearate, glyceryl monostearate, glycerol distearate, and a number of others.

Albin H. Warth
Cape May, New Jersey

WEERMAN DEGRADATION. Formation of an aldose with one less carbon atom from and aldonic acid by a Hoffmann-type rearrangement of the corresponding amid. This is a general reaction of α-hydroxycarboxylic acids.

WEIGHTING AGENT. (1) In soft drink technology, an oil or oil-soluble compound of high specific gravity, such as a brominated olive oil, which is added to citrus flavoring oils to raise the specific gravity of the mixture to about 1.00, so that stable emulsions with water can be made for flavoring. (2) In the textile industry a compound used both to deluster and lower the cost of a fabric, at the same time improving its "hand" or feeling. Zinc acetylacetonate, clays, chalk, etc. are used.

WERNER, A. (1866–1919). A native of Switzerland, Werner was awarded the Nobel prize for his development of the concept of the coordination theory of valence, which he advanced in 1893. His ideas revolutionized the approach to the structure of inorganic compounds and in recent years have permeated this entire area of chemistry. The term *Werner complex* has largely been replaced by "coordination compound".

See also **Coordination Compounds**.

WESSELY-MOSER REARRANGEMENT. Rearrangement of flavones and flavanones possessing the 5-hydroxyl groug, through fission of the heterocyclic ring and reclosure of the intermediate diaroylmethanes in the alternate direction.

WETTING AGENT. A surface-active agent that, when added to water, causes it to penetrate more easily into, or to spread over the surface of, another material by reducing the surface tension of the water. Soaps, alcohols, and fatty acids are examples.

See also **Detergents**.

WHEY PROTEIN. See **Proteins**.

WICHTERLE REACTION. Modification of the Robinson annellation reaction in which 1,3dichloro-*cis*-2-butene is used instead of methyl vinyl ketone

WIDMAN-STOERMER SYNTHESIS. The synthesis of cinnolines by cyclization of diazotized *o*-aminoarylethylenes at room temperature.

WIELAND, HEINRICH O. (1877–1957). A German chemist who won the Nobel prize for chemistry in 1927. His research included work on bile acids, organic radicals, nitrogen compounds, toxic substances, and chemical oxidation, as well as the discovery of the structure of cholesterol. He received his Ph.D. from the University of Munich.

WIGNER FORCE. Short-range nuclear force of nonexchange type postulated phenomenologically as part of the interaction between nucleons. Postulated exchange forces are Bartlett, Heisenberg, and Majorana forces.

WIGNER NUCLIDES. A special case of mirror nuclides. Pairs of odd-mass number isobars for which the atomic number and the neutron number differ by one, and in which the numbers of protons and neutrons are so related that each member of the pair would be transformed into the other by exchanging all neutrons for protons and vice versa.

WILKINSON, GEOFFREY (1921–1996). A British organic chemist who won the Nobel prize for chemistry in 1973 with Ernst Otto Fischer, for their pioneering work, performed independently, on the chemistry of the organometallic, so called sandwich compounds. He was a professor at the University of California and Harvard before returning as professor of inorganic chemistry at the University of London.

WILLEMITE. The mineral willemite is a zinc silicate, Zn_2SiO_4, occurring in hexagonal prisms, as masses or scattered grain. It is a brittle mineral with conchoidal fracture; hardness, 5.5; specific gravity, 3.9–4.2; subvitreous luster; usually some shade of yellow, yellowish-green, green, or reddish-brown, but may be colorless, white, or blue to nearly black; transparent to opaque. Much willemite is strongly fluorescent in yellow or yellowish-green hues. Willemite occurs associated with other zinc materials in Belgium, Algeria, Zaire, South West Africa, and Greenland. In the United States, except for three occurrences, one in Colorado, one in New Mexico, and one in Utah, Sussex County, New Jersey, is the only locality in the United States for willemite and is the only one in which that mineral is found in quantity. Here it is found associated with zincite and franklinite, forming an important ore of zinc. It was named by the French mineralogist, Michel Lévy, in honor of King William the First of the Netherlands.

WILLGERODT REACTION. This reaction, discovered in 1887, is conducted by heating a ketone, for example $ArCOCH_3$, with an aqueous solution of yellow ammonium sulfide (sulfur dissolved in ammonium sulfide), and results in formation of an amide derivative of an arylacetic acid and in some reduction of the ketone. The dark reaction mixture usually is refluxed with

$$ArCOCH_3 + (NH_4)Sx \longrightarrow ArCH_2CONH_2 + ArCH_2CH_3$$

alkali to effect hydrolysis of the amide, and the arylacetic acid is recovered from the alkaline solution. Although the yields are not high, the process sometimes offers the most satisfactory route to an arylacetic acid, as in the preparation of 1-acenaphthylacetic acid from 1-acetoacenaphthene, a starting material made in 45% yield by acylation of the hydrocarbon with acetic acid and liquid hydrogen fluoride. The product is obtained in better yield and is more easily purified than that from an alternate process consisting in hypochlorite oxidation, conversion to the acid chloride, and Arndt-Eistert reaction.

$$\underset{\text{1-Acetoacenaphthene}}{C_{12}H_9COCH_3} \xrightarrow[78\%]{\text{1.KOCl, 2.SOCl}_2} C_{12}H_9COCl \xrightarrow{CH_2N_2} \underset{\text{Diazo ketone}}{[C_{12}H_9COCHN_2]} \xrightarrow[\text{64\%, from acid chloride}]{Ag_2O,\ Na_2S_2O_3} \underset{\text{1-Acenaphthylacetic acid}}{C_{12}H_9CH_2COOH}$$

A modification of the Willgerodt reaction that simplifies the procedure by obviating the necessity of a sealed tube or autoclave consists in refluxing the ketone with a high-boiling amine and sulfur (Schwenk, 1942). Morpholine, so named because of a relationship to an early erroneous partial formula suggested for morphine, is suitable and is made technically by dehydration of diethanolamine. The reaction is conducted in the absence of water, and the reaction product is not the amide but the thioamide; this, however, undergoes hydrolysis in the same manner to the arylacetic acid.

Harvard University
Cambridge, Massachusetts

WILLIAMSON SYNTHESIS. An organic method for preparing ethers by the interaction of an alkylhalide with a sodium alcoholate (or phenolate).

WILLSTATER, RICHARD (1872–1942). A German chemist who won the Nobel prize for chemistry in 1915 or his work on plant pigments, especially chlorophyll. His education was at the University of Munich where he studied and taught before going to Zurich, Switzerland. He researched chlorophylls and pigments of plants and the relationship of cornflower blue to rose red. Work included the study of alkaloids including cocaine, tropine, and atropine. His work perfected the process of chromatographic partition.

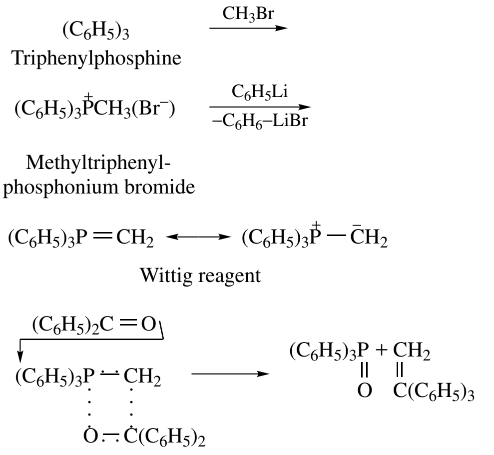
WILZBACH PROCEDURE. Exposure of organic compounds to tritium gas yields tritiated products of high activity without extensive radiation damage. Concentrations of tritium ranging from 1 to 90 millicuries per gram have been obtained with quite varied compounds.

WINDAUS, ADOLF (1876–1959). A German chemist who won the Nobel prize for chemistry in 1928. His work involved the study of steroids and the effect of ultraviolet light activity, ergosterol, and vitamin D_2. He also researched digitalis and histamine. Although he studied medicine, he received his doctorate in chemistry at the University of Freiburg.

WITHERITE. The mineral witherite is barium carbonate, $BaCO_3$, crystallizing in the orthorhombic system. It is interesting to note that at 811°C it changes to the hexagonal system, and at 982°C it appears to become isometric. It has a rather imperfect prismatic cleavage; uneven fracture; hardness 3–3.7; specific gravity, 4.29; luster, vitreous to resinous; color, white to yellowish or grayish; streak, white; transparent to translucent. Witherite is found in veins, and often is associated with galena, as at Alston Moor, Cumberland, England. Associated with barite at Freiberg, Saxony, and at Lexington, Kentucky. Named in honor of Dr. William Withering, an English botanist.

WITTIG, GEORGE (1897–1987). A University of Heidelberg professor who won the Nobel prize for chemistry in 1979 along with Herbert C. Brown of Purdue. Wittig's research showed that phosphorous ylids react with ketones and aldehydes to form alkenes. This reaction is used a great deal in the synthesis of pharmaceuticals and other complex organic substances.

WITTIG REACTION. This reaction provides an excellent method for the conversion of a carbonyl compound to an olefin:



The reagent is unstable and so is generated in the presence of the carbonyl compound by dehydrohalogenation of the alkyltriphenylphosphonium bromide with phenyllithium in dry ether in a nitrogen atmosphere. There are various modifications, such as the phosphonate, in which diethylbenzylphosphonate, cinnamaldehyde, and sodium methoxide yield 1,4-diphenylbutadiene.

Dr. Georg Wittig, University of Heidelberg, was awarded the 1979 Nobel Prize for chemistry for his work in organic synthesis. Dr. Herbert C. Brown of Purdue University also participated in the joint award, but for separate work in organic synthesis.

More details on the early development of the Wittig reaction, dating back to the 1940s, is given in *Science*, **207**, 42–44 (1980).

WOHL DEGRADATION. Method for the conversion of an aldose into an aldose with one less carbon atom by the reversal of the cyanohydrin synthesis. In the Wohl method, the nitrile group is eliminated by treatment with ammoniacal silver oxide.

WÖHLER, FRIEDRICH (1800–1882). A native of Germany, Wöhler working along with Jöns Jakob Berzelius, placed the qualitative analysis of minerals on a firm foundation. In the early 19th century, chemists still thought it impossible to synthesize organic compounds.

Wöhler is regarded as a pioneer in organic chemistry as a result of his (accidental) synthesizing urea in 1828, which electrified the scientific community. Until 1828, it was believed that organic substances could only be formed under the influence of the vital force in the bodies of animals and plants. Wöhler proved by the artificial preparation of urea from inorganic materials that this view was false. Urea synthesis was integral for biochemistry because it showed that a compound known to be produced only by biological organisms could be produced in a laboratory, under controlled conditions, from inanimate matter.

Wöhler was also a co-discoverer of beryllium and silicon, as well as the synthesis of calcium carbide, among others. In 1834, Wöhler and Liebig published an investigation of the oil of bitter almonds. They proved by their experiments that a group of carbon, hydrogen, and oxygen atoms can behave like an element, take the place of an element, and can be exchanged for elements in chemical compounds. Thus the foundation was laid of the doctrine of compound radicals, a doctrine which had a profound influence on the development of chemistry.

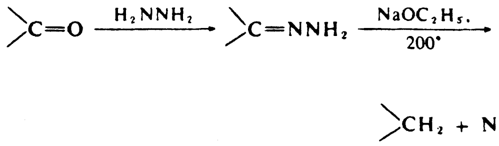
Wöhler's discoveries had great influence on the theory of chemistry. Journals from 1820 to 1881 contained contributions from him. The sum of his work is absolutely overwhelming.

WÖHLER SYNTHESIS. Classical synthesis of urea by heating an aqueous solution of ammonium cyanate extended to preparation of urea derivatives.

WOHLWILL PROCESS. The official process of the U.S. mints for refining gold. It consists of subjecting gold anodes to electrolysis in a hot solution of hydrochloric acid containing gold chloride, the solution being continuously agitated with compressed air.

WOLFFENSTEIN-BOTERS REACTION. Simultaneous oxidation and nitration of aromatic compounds to nitrophenols with nitric acid or the higher oxides of nitrogen in the presence of a mercury salt as catalyst. Hydroxynitration of benzene yields picric acid.

WOLFF-KISHNER REACTION. This method of reduction was discovered independently in Germany (Wolff, 1912) and in Russia (Kishner, 1911). A ketone (or aldehyde) is converted into the hydrazone, and this derivative is heated in a sealed tube or an autoclave with sodium ethoxide in absolute ethanol.



After preliminary technical improvements, Huang Minlon (1946) introduced a modified procedure by which the reduction is conducted on a large scale at atmospheric pressure with efficiency and economy. The ketone is refluxed in a high-boiling water-miscible solvent (usually di- or triethylene glycol) with the aqueous hydrazine and sodium hydroxide to form the hydrazone; water is then allowed to distil from the mixture till the temperature rises to a point favorable for decomposition of the hydrazone (200°); and the mixture is refluxed for three or four hours to complete the reduction.

Harvard University
Cambridge, Massachusetts

WOLFF REARRANGEMENT. Rearrangement of diazoketone to ketenes by action of heat, light or some metallic catalyst. The rearrangement is the key step in the Arndt-Eistert synthesis.

WOLFRAMITE. The mineral wolframite, tungstate of iron and manganese, is an isomorphous mixture of tungstate of iron, $FeWo_4$, and tungstate of manganese, $MnWO_4$, the amounts being variable. The pure iron tungstate is called ferberite and the manganese tungstate, hübnerite. It has been proposed that the name ferberite be applied to mixtures of not less than 80% $FeWO_4$ and not more than 20% $MnWO_4$, and that the term hübnerite be given to mixtures of not less than 80% $MnWO_4$ but not more than 20% $FeWO_4$. Wolframite would thus include the minerals of intermediate composition, and its formula would be written $(Fe^{2+}, Mn)WO_4$. Wolframite is monoclinic, usually appearing in tabular, columnar or bladed crystals, sometimes quite large; also may be massive. Its hardness is 4–4.5; specific gravity, 7.371; color, gray, reddish-brown, brown or black; streak, reddish-brown to black; luster, submetallic; opaque, occasionally magnetic.

Wolframite is found associated with apatite, cassiterite, quartz, and fluorite; in granites and pegmatites. Often with scheelite, $CaWO_4$, and

sometimes as a pseudomorph after that mineral. Wolframite is found in the Czech Republic and Slovakia, Rumania, Saxony, Cornwall in England, New South Wales, Bolivia; and in the United States at Trumbull, Connecticut; Luna and Lincoln Counties, New Mexico. It also occurs in small quantities in Nevada and Utah.

Ferberite, which has monoclinic tabular crystals, sometimes massive, resembles wolframite, and occurs in Spain and in Boulder County, Colorado. Superb crystals of Ferberite in association with apatite and arsenopyrite crystals occur at Panasqueira, Portugal.

Hübnerite crystals are monoclinic, often long fibrous or bladed, may be massive; resembles wolframite and is found in Peru, the Black Hills, South Dakota; San Juan County, Colorado; White Pine County, Nevada, and Lemhi County, Idaho.

WOLLASTONITE. The mineral wollastonite is calcium metasilicate, $CaSiO_3$, which is found as tabular or short prismatic triclinic crystals. This mineral has a hardness of 4.5–5; specific gravity, 2.87–3.09; color, white to gray, rarely green to colorless; luster, vitreous to pearly; transparent to translucent. Wollastonite in the main is formed by the action of contact metamorphic processes on limestones at relatively high temperature (600°C+). Its common associates, diopside, vesuvianite, garnet and epidote, suggest this origin. Some of the more important localities are in the copper mines of Rumania, in the lavas of Monte Somma and Vesuvius, in Finland and Mexico. In the United States it is found in Essex and Lewis Counties, New York; Keweenaw County, Michigan; and Riverside County, California. Wollastonite was named in honor of the English chemist, William Hyde Wollaston.

WOOD. A vascular tissue which occurs in all higher plants. The most important commercial sources of wood are the gymnosperms, or softwood trees and the dicotyledonous angiosperms, or hardwood trees. Botanically, wood serves the plant as supporting and conducting tissue, and it also contains certain cells which serve in the storage of food. The trunks and branches of trees and shrubs are composed of wood, except for the very narrow cylinder of pith in the center and the bark which covers the outside. Botanists refer to wood by its Greek name, *xylem*.

A new cylinder of wood is laid down each year around the previously formed wood in the tree. This new growth originates in the cambium, a very narrow growing layer, which elaborates both the wood and the bark, and which separates these two tissues from each other. Each year's growth of wood forms a new concentric ring in the woody-stem, as viewed in cross-section. These are termed the annual rings. Each of these has an inner part (toward the pith) which is laid down in the early growing season and is termed the spring wood and an outer layer (towards the bark) which is laid down later and is known as summer wood. The cell walls of the latter are often thicker, forming a denser structure than the spring wood.

Most of the cells of wood are long, narrow hollow fibers and tubular-shaped cells arranged with their long axes parallel to the axis of the tree trunk. Certain food storage cells lie in radial bands, termed wood rays, which are perpendicular to the tree axis. The walls of this complex system of plant cells form the basic framework and material of all wood substance. All wood substance is composed of two basic chemical materials, *lignin*, and a polysaccharidic system, which is termed *holocellulose*. The latter embraces *cellulose* and the *hemicelluloses*, a mixture of pentosans, hexosans and polyuronides, and in some instances small amounts of pectic materials. Wood cell wall tissue also always retains small amounts of mineral matter (ash).

The outer portion of the cell wall, known as the primary wall, is heavily lignified. The intercellular substance, termed the middle lamella, is mainly lignin. The lignin of the middle lamella and primary walls thus serves as a matrix in which the cells are imbedded. Dissolution and removal of the lignin results in separation of the wood fibers. This is the underlying principle in the manufacture of chemical pulps from wood for paper or other cellulose products. **Papermaking and Finishing**; and **Pulp (Wood) Production and Processing**.

About one-fourth or more of the lignin is in the middle lamella-primary wall complex. The remainder is within the holocellulose system of the cell walls.

Besides the cell wall tissue, which is the basic material of all wood substance, wood contains a variety of materials, many of which may be extracted by selected solvents. These extraneous components lie mainly within the cavities (lumen of the cells and on the surfaces of the cell walls. These "extraparietal substances" include a wide range of chemically different materials, such as essential oils, aliphatic hydrocarbons, fixed oils, resin acids, resinols, tannins, phytosterols, alkaloids, dyes, proteins, water-soluble carbohydrates, cyclitols, and salts of organic acids. The amount and composition of these extraneous substances vary greatly. The occurrence of certain of these substances is often very specific as to genera or species. Generally, however, the total amount of the extraneous components is only a few percent of the total weight of the wood.

The chemical composition of the extractive-free wood, i.e., the cell wall substance varies less than do the extractives. However, it is by no means constant, there being major differences between hardwoods and softwoods, and often between different genera and even between species. There is even some variability in chemical composition within the same log. For example, there is more lignin in the thinner-walled spring wood than in the summer wood, and more lignin in wood ray cells than in the tracheids or fibers. The heart-wood tissue often contains greater deposits of extraneous (extractive) components than the sapwood. There are major differences between most softwoods (conifers) and most temperate zone hardwoods (broad-leaf trees). Usually the softwoods have greater amounts of extraneous components extractable by organic solvents. Generally the lignin content of softwoods is higher than that of hardwoods, *viz.*, in the order of 25–30% compared to 17–24%. Also there is a major difference in the pentosan content between these two groups of woods, the hardwoods containing usually about 17–22% and the softwoods about 8–14%. There are exceptions to these generalizations, however.

The components of the cell wall substance of wood are exceedingly difficult to separate. Separations are rarely complete and generally bring about drastic chemical changes, especially in the lignin and molecular size degradation of the polysaccharides. To a considerable extent the components are apparently interpenetrating polymer systems. The long-chain linear polysaccharides tend to be parallel to the fiber axis and to form areas of varying degrees of crystallinity, as shown by x-rays and other physical and chemical properties. The lignin appears to be an amorphous tridimensional polymer.

Wood forms one of the world's most important chemical raw materials. It is the primary source of cellulose for the pulp and paper and cellulose industries. These industries are well up in the group of 10 major industries of the United States. For paper, rayon, films, lacquers, explosives and plastics, which comprise the greatest chemical uses of wood, it is the cellulose component (plus certain amounts of hemicellulose) of wood that is of value. The lignin forms a major industrial waste as a by-product of the paper and cellulose industries. Its major use is in its heat value in the recovery of alkaline pulping chemicals. A variety of minor uses for lignin have been developed, such as for the manufacture of vanillin, adhesives, plastics, oil-well drilling compounds and fillers for rubber.

Wood wastes from the lumber and woodworking industries form a great potential source of sugars and alcohol by acid hydrolysis of its polysaccharides followed by fermentation. Wood hydrolysis processes, however, are not yet economically competitive with other sources of sugars and alcohol in this country and many other areas of the world.

Wood is also an industrial source of charcoal, tannin, rosin, turpentine, and various other essential oils and pharmaceutical products.

WOOD (As Energy Source). See **Wastes as Energy Sources**.

WOOD PRESERVATIVE. A material applied to wood to prevent its destruction by fungi, wood-boring insects, marine borers and fire. A common characteristic of these materials is toxicity to those organisms that attack wood, or in the case of fire retardants the ability to control combustion in terms defined by the Underwriters Laboratory. In addition, a satisfactory wood preservative must also (a) be capable of penetrating wood, (b) remain in the wood for extended periods without losing its effectiveness due to chemical breakdown, (c) be harmless to humans and animals, (d) be noncorrosive and, (e) be available in quantity at a reasonable cost. For certain uses, the preservative may be required to be colorless, odorless, nonswelling and paintable.

The principal wood preservatives in use today are classified as (a) preservative oils, (b) toxic chemicals in organic solvents, and (c) water-soluble salts.

The most important of the preservative oils is coal-tar creosote and its solutions in the form of creosote-coal tar and creosote petroleum. Coal-tar creosote is defined by the American Wood Preservers Association as—"A distillate of coal tar produced by high-temperature carbonization of bituminous coal; it consists principally of liquid and solid aromatic hydrocarbons and contains appreciable quantities of tar acids and tar bases; it is heavier than water and has a continuous boiling range of at least 125°C, beginning at about 200°C." This material is one of the oldest wood preservatives and is regarded by many as the best substance known for protection against all forms of wood-destroying organisms. For normal service conditions, minimum retentions of 8–10 lb/ft^3(128–161 kg/m^3) of wood penetrated are sufficient. For extreme conditions, retentions as high as 35 lb/ft^3(561 kg/m^3) are desirable. Currently, coal-tar creosote and creosote solutions are used as preservatives for about 60% of all wood products treated.

Of the large number of toxic chemicals that are oil-soluble, only three are recognized by the American Wood Preservers Association and only one of these is a commercially important wood preservative, pentachlorophenol (C_6Cl_5OH). Although "penta" is effective against fungi and insects, it will not protect against marine borers, and hence cannot be used as a wood preservative for salt water installations.

The two most common solvents for carrying penta into the wood are a relatively high-boiling No. 2 fuel oil and a very low-boiling liquified petroleum gas, butane. When fuel oil is used it remains in the wood and although the end product is brighter and cleaner than creosote-treated wood, it has a somewhat oily character and cannot readily be painted. When LP gas is used as the solvent, the butane is recovered and the penta is deposited in the wood as a dry crystalline material, hence the wood retains its color and is readily paintable.

Water-borne preservatives are divided into two categories. One group which includes acid copper chromate, chromated zinc chloride, copperized chromated zinc arsenate and fluorchrome-arsenate-phenol is used where the wood is not subjected to excessive leaching. The second group, ammoniacal copper arsenite and three types of chromated copper arsenate which react to become practically water insoluble, are used at about 0.6 lb/ft^3(9.6 kg/m^3) when wood is placed in ground contact under severe service conditions.

Water-borne preservatives penetrate wood easily and the solution presents no problem in flammability or health hazards. Disadvantages of water soluble preservatives include the swelling and shrinking of the treated material, reduction in bending strength and stiffness as a result of failure to redry following treatment, and less protection against weathering and mechanical wear than provided by either preservative oils or oil soluble chemicals in which the solvent remains in the wood.

In addition to the general preservative categories discussed there is a fourth group known as "proprietary preservatives" which are composed of various combinations of toxic materials and solvents. These are sold under trade names and in some cases are protected by patents.

While wood preservatives can be applied by simple means such as brushing, spraying and cold soaking, well over 90% of all commercial wood treatment is by one of the "pressure processes." Although the details of the individual processes vary, the type of equipment and general procedure used are similar. Treatment takes place in closed cylinders 6–9 feet (1.8-2.7 m) in diameter and up to 180 feet (54 m) in length. The wood to be treated is placed in the retort, submerged in the preservative and subjected to pressures in the order of 200 psi (13.6 atm). The preservative is often at an elevated temperature and in some cases the wood is given a preliminary pressure or vacuum period prior to admitting the preservative into the retort.

The most satisfactory nonpressure process is known as "thermal" treatment. The wood to be treated is immersed in a preservative at an elevated temperature. This causes the air in the wood cells to expand so that when the wood is transferred into a preservative bath of lower temperature, the air contracts forming a partial vacuum and atmospheric pressure forces the liquid into the wood.

Although the fire retardant treatment of wood is essentially the injection of water soluble salts into the wood by pressure treating methods, it deserves separate mention if for no other reason than the higher salt retention (4lbs/cu. ft. vs. 0.6 lbs/cu. ft.) (64 kg/m^3 vs 9.6 kg/m^3) required. Most fire retardant treatments are proprietary and are specified by the Underwriters Laboratory on the basis of flame spread ratings. The latter's list of building materials will give details of the ratings including those of a recently introduced leach-resistant fire retardant suitable for outdoor service. Common fire-retardant chemicals include diammonium phosphate, ammonium sulfate, sodium tetraborate and boric acid which are used in various combinations.

WOOD PULP. See **Pulp (Wood) Production and Processing**.

WOODWARD-HOFFMANN RULES. Rules that predict the stereochemical course of concerted reactions in terms of the symmetry of the interacting molecular orbitals.

WOODWARD, ROBERT B. (1917–1979). An American chemist born in Quincy, MA, and widely regarded as one of the world's leading synthetic organic chemists. After receiving his doctorate from M.I.T. (the youngest student in the history of the institute to do so) he joined the Harvard faculty in 1937 as instructor and attained full professorship in 1950. He was recipient of the Nobel prize in 1965 for his brilliant work in synthesizing complex organic compounds, among them quinine, cholesterol, chlorophyll, reserpine, and cobalamin (vitamin B_{12}). When he died in 1979, his synthesis of the antibiotic erythromycin was virtually complete, and finished by his associate's two years later. He was director of the Woodward Research Institute in Basel, Switzerland, and a member of the governing board of the Weizmann Institute in Israel.

WOOL. The natural, highly crimped fiber from sheep, wool is one of the oldest fibers from the standpoint of use in textiles. Minute scales on the surface of the fibers allow them to interlock and are responsible for the ability of the fiber to *felt*, a phenomenon responsible for felt cloth and mill-finished worsteds. Crimpiness in wool is due to the open formation of the scales. Fine merino wool has 24 crimps per inch (~10 per centimeter). Luster of the fiber depends upon the size and smoothness of the scales. The basic wool protein, *keratin*, comprises molecular chains that are linked with sulfur. When sulfur is fed to sheep in areas deficient of the element, the quality of the wool improves. Wool fibers that fall below 3 inches (7.5 centimeters) in length are known as *clothing wool*; fibers 3–7 inches (7.5–17.8 centimeters) long are referred to as *combing wools*. The wool-fiber diameter ranges from 0.0025 to 0.005 inch (0.06–0.13 millimeter). See also **Fibers**.

WROUGHT IRON. A ferrous material aggregated from a solidifying mass of pasty particles of highly refined metallic iron, with which, and without subsequent fusion, is included a minutely and uniformly distributed quantity of slag. This definition of wrought iron indicates that it is a material made of two components; one, iron of a high degree of purity, the other, slag (chiefly silicate of iron). In the finished product the slag is distributed through the iron in threads and fibers, of which there is an enormous number. The slag imparts to the wrought iron a fibrous structure, quite different from the crystalline structure of cast metals. Wrought iron has made for itself a name as a metal which has resistance to corrosion, and which is exceptionally suitable for structural purposes where the structure is subject to shock. Wrought iron also can be readily worked, forged, machined, welded, galvanized, etc. Among the many applications of wrought iron might be mentioned tubes, pipes, and tanks.

WULFENITE. The mineral wulfenite is lead molybdate corresponding to the formula $PbMoO_4$, analyses showing that a part of the lead may be replaced by calcium. Wulfenite crystallizes in the tetragonal system usually in thin tabular forms, but is also found massive. It is a brittle mineral; hardness, 2.75–3; specific gravity, 6.5–7; luster, adamantine to resinous; color, yellowish to green or red, may be whitish or grayish; transparent to translucent. Wulfenite is a secondary mineral found in association with other lead minerals such as galena, and pyromorphite. It is believed to have been formed, at least in part, by the action of waters containing molybdenum salts on cerussite, anglesite, and pyromorphite.

Especially important localities are in the former Yugoslav Republics, the Czech Republic and Slovakia, Morocco, Zaire, New South Wales and Mexico. In the United States it has been found in Phoenixville, Pennsylvania, and in the Organ Mountains, New Mexico; Yuma County,

Arizona; Box Elder and Salt Lake Counties, Utah; and in Clark and Eureka Counties, Nevada. Wulfenite was named in honor of F.X. von Wülfen, an Austrian mineralogist of the eighteenth century.

WÜRTZ-FITTIG-FRANKLAND REACTION. Sodium metal was used by Würtz as reagent for the preparation of paraffin hydrocarbons by treating alkyl iodide in ethereal solution, thus:

C_2H_5I	Na	(Ether) →	C_2H_5	NaI
C_2H_5I	Na		C_2H_5	NaI
Ethyl iodide	Sodium		Normal-butane	Sodium iodide

The method has been applied to the preparation of paraffin hydrocarbons as high in the series as hexacontane $C_{60}H_{122}$. The alkyl radicals may be the same or different in the iodide or iodides taken.

Sodium metal was also used similarly by Fittig as reagent for the preparation of hydrocarbons by treating aryl bromide or iodide in the presence of dry ether, thus:

C_6H_5Br	Na	(Ether) →	C_6H_5	NaBr
C_6H_5Br	Na		C_6H_5	NaBr
Phenyl iodide	Sodium		Biphenyl	Sodium bromide

When alkyl iodide and aryl bromide are taken, the hydrocarbon is of the mixed alkyl-aryl type, thus:

CH_3I	Na	(Ether) →	CH_3	NaI
C_6H_5Br	Na		C_6H_5	NaBr
Methyl iodide Phenyl bromide	Sodium		Toluene	Sodium iodide Sodium bromide

CH_3I	Na	(Ether) →	C_6H_4 < CH_3 (1), CH_3 (4)	NaI
C_6H_4 < CH_3 (1), Br (4)	Na			NaBr
Methyl iodide *Para*-bromo-toluene	Sodium		*Para*-xylene	Sodium iodide Sodium bromide

The method has been applied to the preparation of substituted benzene hydrocarbons containing as many as four alkyl-groups (durene, $C_6H_2(CH_3)_4$(1,2,4,5) and isodurene, $C_6H_2(CH_3)_4$(1,2,3,5)).

Frankland introduced the use of zinc instead of sodium to accomplish similar reactions. See also **Fitting Reaction**; and **Organic Chemistry**.

WURTZITE. A mineral zinc sulfide, (Zn, Fe)S, similar to sphalerite. Crystallizes in the hexagonal system. Hardness, 3.5–4; specific gravity, 3.98; color, brownish-black with resinous luster. Named after Adolphe Würtz, France.

X

XALSTOCITE. A pink to rose-pink variety of grossular garnet. Sometimes also called landerite or rosolite.

XANTHAN GUM. A very high-molecular-weight polysaccharide produced by pure culture fermentation of glucose by *Xanthamonas campestris*. The substance is readily soluble in hot or cold water, imparting a high viscosity at low concentrations. The solutions are pseudoplastic, with viscosity decreasing rapidly as shear rate increases. Heat, acid, and salt have little effect on the stability of its solutions. The substance is compatible with most other hydrocolloids, including starch. Xanthan gum undergoes a unique gel reaction with locust bean gum to produce a synergistic increase in viscosity. The gum is used as a thickening, suspending, emulsifying, and stabilizing agent in foods and has a number of important nonfood uses as well.

In 1974, the Northern Regional Research Center (Peoria, Illinois) of the U.S. Department of Agriculture and the Kelco Company were joint recipients of the Institute of Food Technologists award for the development and commercialization of xanthan gum. As early as 1956, researchers discovered unusual water-thickening abilities of a substance produced by the bacterium *Xanthamonas campestris*. They chemically identified the substance and named it *Polysaccharide B-1459* after the culture number. A food additive regulation for its use (when it was renamed xanthan gum) was issued in 1959. The process was brought into commercial production in 1964.

Glucose from starch is fermented by the aforementioned bacteria to produce xanthan gum, which is recovered by precipitation with isopropyl alcohol, then washed, dried, and milled. Among several applications, xanthan gum is used in pourable salad dressings for its emulsifying properties; in frozen foods for its freeze-thaw stabilizing effect; in juice drinks for its suspending properties; and in creamed cottage cheese for its stabilizing properties, pseudoplasticity, and mouthfeel. The gum makes a stable cream dressing that clings to the curd, but shears easily and thus does not have a gummy texture. The gum is also used as a stabilizer for frozen desserts and as a suspending agent in liquid feed supplements for cattle feeding and in milk replacers for calves. It also has been found that xanthan gum makes the proteins in nonwheat breads more extensible and thus produces better breads.

For references see the list in the entry on **Colloid Systems**. Other gums and mucilages are described in the entry on **Gums and Mucilages**.

XANTHATES. The salts of the *O*-esters of carbonodithioic acids and the corresponding *O,S*-diesters are xanthates. The free acids decompose on standing.

Properties

The free xanthic acids are unstable, colorless, or yellow oils, and may decompose with explosive violence. They are soluble in the common organic solvents and are slightly soluble in water: methyl xanthic acid at 0°C, 0.05 mol/L; ethyl xanthic acid at 0°C, 0.02 mol/L; and *n*-butyl xanthic acid at 0°C, 0.0008 mol/L. Values for the dissociation constant for ethyl xanthic acid are $(2.0-3.0)\times 10^{-2}$. Potentiometric determinations for C_1-C_8 xanthic acids show a decreasing acid strength with increasing molecular weight. The alkali metal salts, in contrast to the free acids, are relatively stable solids, are pale yellow when pure, and sometimes have a disagreeable odor.

When exposed to air, the sodium salts tend to take up moisture and form dihydrates. The alkali metal xanthates are soluble in water, alcohols, the lower ketones, pyridine, and acetonitrile (Table 1). They are not particularly soluble in nonpolar solvents.

The heavy metal salts, in contrast to the alkali metal salts, have lower melting points and are more soluble in organic solvents. They are slightly soluble in water, alcohol, aliphatic hydrocarbons, and ethyl ether. Alkalies stabilize xanthate solutions somewhat and the solutions readily decompose at acidic pHs.

TABLE 1. SOLUBILITIES OF SOME ALKALI-METAL XANTHATES

		Solubility, g/100 g soln			
Xanthate	Solvent	0°C	10°C	20°C	35°C
sodium ethyl	water	40.8	46.0	52.0	
potassium *n*-propyl	water	43.0			58.0
	n-propyl alcohol	1.9			8.9
sodium *n*-propyl	water	17.6			43.3
	n-propyl alcohol	10.2			22.5
potassium isopropyl	water	16.6			37.2
	isopropyl alcohol				2.0
	IPA-H_2O azeotrope			6.9	
sodium isopropyl	water	12.1			37.9
		24.5	27.3	30.5	
		24.0	27.5	31.0	37.5
	isopropyl alcohol				19.0
potassium *n*-butyl	water	32.4			47.9
	n-butyl alcohol				36.5
sodium *n*-butyl	water	20.0			76.2
	n-butyl alcohol				39.2
potassium isobutyl	water	10.7			47.7
	isobutyl alcohol	1.6			6.2
sodium isobutyl	water	11.2			33.4
		46.2	48.2	50.5	
		44.0	49.0	51.0	57.3
	isobutyl alcohol	1.2			20.5
sodium *sec*-butyl	water	29.4	34.0	38.8	
potassium isoamyl	water	28.4			53.5
		16.9	26.0	35.0	
		28.5	39.0	45.6	52.5
	isoamyl alcohol	10.9			15.5

Reactions. The chemistry of the xanthates is essentially that of the dithio acids.

Peroxyxanthates. A new factor in the theory and practice of flotation was found in the Mount Isa, Australia, copper flotation solution. Secondary butyl perxanthate was formed by the reaction of the xanthate with hydrogen peroxide in dilute alkaline aqueous solution and was found to be identical to a substance from the flotation solution. The perxanthate was isolated as the ammonium salt.

Preparation and Manufacture

The alkali metal xanthates are generally prepared from the reaction of sodium or potassium hydroxide with an alcohol and carbon disulfide.

Many of the heavy metal xanthates have been prepared from aqueous solutions of the alkali metal xanthates and the water-soluble compound of the heavy metal desired.

Alkali Metal Xanthates. The commercially available xanthates are prepared from various primary or secondary alcohols. The alkyl group varies from C_2 to C_5 and the alkali metal may be sodium or potassium.

The alkali metal xanthates are fairly safe to handle. The standard precautions of rubber gloves, dust mask, and goggles are sufficient when handling the solid or the solution.

Under regulations for the enforcement of the Federal Insecticide, Fungicide, and Rodenticide Act, products containing over 50 wt % sodium isopropyl xanthate must bear the label "Caution. Irritating dust. Avoid breathing dust, avoid contact with skin and eyes". Rubber goods in repeated

contact with food may contain diethyl xanthogen disulfide not to exceed 5 wt % of the rubber products.

Xanthate drums should be kept as cool and dry as possible. Protection from moisture is the most important factor. A combination of moisture and hot weather causes sodium ethyl xanthate to ignite spontaneously.

Environmental Concerns. Concern for the well-being of the environment has resulted in studies on the effects of mining chemicals, including the xanthates, on various aquatic organisms worldwide. In a thorough and detailed study of three typical mill operations, it was concluded that residual organic flotation reagents do not seem to present widespread problems in effluent disposal.

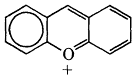
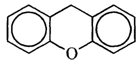
XANTHENE DYES. Xanthene dyes are those containing the xanthylium (**1a**) or dibenzo-γ-pryan nucleus (xanthene) (**1b**) as the chromophore with amino or hydroxy groups meta to the oxygen as the usual auxochromes. They are important because of their brilliant hues; shades between greenish yellows to dark violets and blues are obtainable, the most important being reds and pinks. Xanthenes are often fluorescent, which adds to their strength and brightness; but, as is often the case with fluorescent dyes, they have lower light-fastness compared to other chromophores. Their use is concentrated on those areas in which light-fastness is relatively unimportant compared to economy (e.g., paper dyes) or where lightfastness can be achieved by modification. They are used for the direct dyeing of wool and silk and mordant dyeing of cotton. Paper, leather, woods, food, drugs, and cosmetics are dyed with xanthene dyes. See also **Dyes**.

Brilliant insoluble lakes are used in paints and varnishes. Recent applications for xanthene dyes include use in ink-jet printers, as markers in biological and medical research, and even as insecticides.

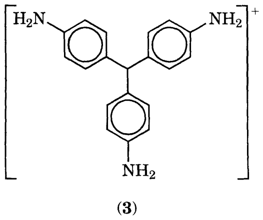


(1a)

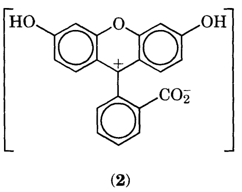


(1b)

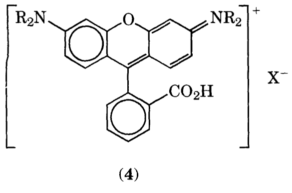
Xanthenes date from 1871 when von Bayer synthesized fluorescein (**2**).



(3)



(2)

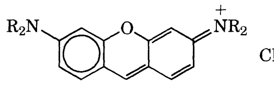


(4)

The xanthene dyes may be classified into two main groups: diphenylmethane derivatives, called pyronines, and triphenylmethane derivatives (e.g., (**3**)), which are mainly phthaleins made from phthalic anhydride condensations. A third much smaller group of rosamines (9-phenylxanthenes) is prepared from substituted benzaldehydes. The phthaleins may be further subdivided into the following: fluoresceins (hydroxy substituted); Rhodamines (amino substituted), e.g., (**4**); and mixed hydroxy/amino substituted.

Diphenylmethane Derivatives

Pyronines. Pyronines are diphenylmethane derivatives synthesized by the condensation of *m*-dialkylaminophenols with formaldehyde, followed by oxidation of the xanthene derivative to the corresponding xanthydrol, which in the presence of acid forms the dye (**5**). If R is methyl, the dye is pyronine G (CI 45005); if R is ethyl, pyronine B (CI 45010) is obtained.



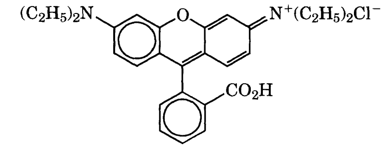
(5)

Succineins. Succineins are carboxyethyl-substituted pyronines made by substituting succinic anhydride for formaldehyde in the basic synthesis.

Triphenylmethane Derivatives

Amino-Derivatives

Rhodamines. Rhodamines are commercially the most important aminoxanthenes. If phthalic anhydride is used in place of formaldehyde in the above condensation reaction with *m*-dialkylaminophenol, a triphenylmethane analogue, 9-phenylxanthene, is produced. Historically, these have been called rhodamines. Rhodamine B (Basic Violet 10, CI 45170) (**6**) is usually manufactured by the condensation of two moles of *m*-diethylaminophenol with phthalic anhydride.



(6)

The rhodamines described thus far are basic rhodamines. They are used primarily for the dyeing of paper and the preparation of lakes for use as pigments. They are also used in the dyeing of silk and wool where brilliant shades with fluorescent effects are required, but where light-fastness is unimportant. Many new uses for rhodamine dyes have been reported. For example, when vacuum-sublimed onto a video disk, Rhodamine B loses its color to form a clear stable film which becomes permanently colored on exposure to uv light. This can be used in optical recording for computer storage or video recording. Acid rhodamines are made by the introduction of the sulfonic acid group to the aminoxanthene base.

Some acid rhodamines are used for silk and wool. Highly substituted acid rhodamines have been reported for fiber-reactive dye applications.

Rosamines. Rosamines are 9-phenylxanthene derivatives prepared from substituted benzaldehydes instead of phthalic anhydride. Sulforhodamine B (Acid Red 52; CI 45100) is the most important rosamine.

Hydroxyl Derivatives. The building block of most hydroxyl-substituted xanthenes, or fluorones, is fluorescein (**2**). The sodium or potassium salt of fluorescein, commonly called uranine (CI 45350), is used for dyeing wool and silk brilliant yellow shades. However, the principal use of fluorescein is as an intermediate for more highly substituted hydroxyxanthenes.

Aminohydroxy Derivatives

Aminohydroxy-substituted xanthenes are of little commercial importance. They are synthesized by condensing one mole of *m*-dialkylaminophenol with phthalic anhydride, and then condensing that product with an appropriately substituted phenol.

Miscellaneous Derivatives

Two additional xanthene analogues are termed fluorescent brighteners. Fluorescent Brightener 74 (CI 45550) and Fluorescent Brightener 155 (CI 45555) are used in the formulation of solid dielectric compositions for application in high voltage cables to prevent conductive treeing.

Health and Safety Factors, Toxicology

Xanthene dyes have not exhibited health or safety properties warranting special precautions; however, standard chemical labeling instructions are required.

XANTHOPHYLLS. See **Carotenoids**.

XENOBLAST. A term proposed by Becke in 1903 for metamorphic crystals with undeveloped crystal faces.

XENOCRYST. A term proposed by Sollas in 1894 for crystals, usually corroded, which are foreign to the magma from which the igneous rock in which they occur has crystallized.

XENOLITH. A fragment, large or small, of a foreign rock included in an igneous mass. The term is derived from the Greek, meaning stranger and stone. Xenoliths, both large and small, are best displayed at the contacts or margins of batholiths.

XENOMORPHIC. The texture or fabric of an igneous rock having or characterized by crystals not bounded by their own crystal faces and which have their form impressed upon them by preexisting adjacent mineral crystals.

XENON. [CAS: 7440-63-3]. Chemical element, symbol Xe, at. no. 54, at. wt. 131.30, periodic table group 18 (inert or noble gases), mp. $-112°C$, bp $-107.1 \pm 2.5°C$, density 3.5 g/cm^3 (liquid at $-109°C$). Specific gravity compared with air is 4.561. Xenon was found by Travers and Ramsay in 1898 when they were experimenting with liquefied air. Solid xenon has a face-centered cubic crystal structure. At standard conditions, xenon is a colorless, odorless gas and does not form stable compounds with any other element. Due to its low valence forces, xenon does not form diatomic molecules, except in discharge tubes. It does form compounds under highly favorable conditions, as excitation in discharge tubes, or pressure in the presence of a powerful dipole. Xenon forms a hydrate much more readily than argon, at a pressure slightly above 1 atmosphere pressure at 0°C. The element also forms additional compounds with a number of organic substances, such as $Xe \cdot 2C_6H_5OH$ with phenol, which has a dissociation pressure of 1 atmosphere at 4°C. See also **Chemical Elements**.

In 1962, the compound xenon platinum hexafluoride was synthesized by Bartlett. Later in the same year, Classen confirmed the synthesis and prepared the first binary compound of an inert gas, xenon tetrafluoride, a stable crystalline compound, mp about 90°C. The compound was prepared by heating a 5:1 mixture of fluorine and xenon to 400°C, then cooling it rapidly to room temperature. Since the original research, additional xylene-fluroine compounds have been reported, including XeF_2, XeF_4, XeF_6, XeF_6, $XeSiF_6$, XeO_2F_2, and Na_4XeO_6, as well as the hydrate. By heating xenon and fluorine above 10 atmospheres (up to 170 atmospheres), at 250°C, Weinstock, Weaver, and Krop obtained XeF_5 and XeF_6 in an equilibrium mixture. D.F. Smith, S.M. Williamson, and C.W. Koch have reported the preparation of XeO_3 from the hexafluoride and tetrafluoride. XeO_3 is a white, crystalline, explosive compound.

Xenon also forms compounds, possibly clathrates, with certain substances in nonstoichiometric proportions. Crystalline compounds with benzene or hydroquinone, formed under 40 atmospheres pressure, contain about 26% xenon by weight. Alkaline hydrolysis of XeF_6 produces salts of octavalent xenon. No persistent divalent or tetravalent compounds are found in aqueous solution, but the former is intermediate in hydrolysis of the fluorides, and the latter in reactions of XeO_3 with XeF_2, H_2O_2, and various organics.

Xenon occurs in the atmosphere to the extent of approximately 0.00087%, making it the least abundant of the rare of noble gases in the atmosphere. In terms of abundance, xenon does not appear on lists of elements in the earth's crust because it does not exist in stable compounds under normal conditions. However, xenon because of its limited solubility in H_2O, is found in seawater to the extent of approximately 950 pounds per cubic mile (103 kilograms per cubic kilometer). Commercial xenon is derived from air by liquefaction and fractional distillation. There are nine natural isotopes ^{124}Xe, ^{126}Xe, ^{128}Xe, through ^{132}Xe, ^{134}Xe, and ^{136}Xe, and seven radioactive isotopes ^{123}Xe, ^{125}Xe, ^{127}Xe, ^{133}Xe, ^{135}Xe, ^{137}Xe and ^{138}Xe, all with relatively short half-lives, the longest ^{127}Xe with a half-life of about 36 days. See also Radioactivity. First ionization potential, 12.127 eV; second, 21.1 eV; third, 32.0 eV. Van der Waals radius 2.20 Å Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 5s^2 5p^6$.

Xenon is one of the elements of interstellar matter that is found in some meteorites. As reported by Lewis and Anders (1983), at least three types of xenon are present in carbonaceous chondrites. Two are abundant but controversial; the third is rare, but easy to explain. In 1964, Reynolds and Turner (University of California at Berkeley) examined the C2 chondrite Renazzo and were seeking xenon 129 (from radioactive decay of iodine 129). A controlled, step-heating process was used. In addition to finding xenon-129, the investigators found that in the fractions released between 600 and 1100°C, the heavy isotopes of Xe ranging in mass from 131 through 136 were present. They found that these isotopes were enriched by as much as 6% with respect to primordial xenon. This enrichment increased from isotope 131 to isotope 136, as it does in the xenon formed by the fission of uranium and other heavy elements. Reynolds and Turner thus suggested that the new xenon component came from the fission of some extinct heavy element that had once been present in the meteorite. It was also noted that xenon 124 and 126 were also enriched in the meteorite, but inasmuch as these isotopes do not form by fission, their enrichment was not fully explained. The two sets of xenon components have been named H (heavy) and L (light) and, although apparently of different origins, they have proved inseparable in meteorites. Xenon also has been detected in some of the planetary atmospheres, such as that of Mars. Check various entries on planets in this book.

The gas finds principal application in special electronic devices and lamps. Xenon, in a vacuum tube, produces a beautiful blue glow when excited by an electrical discharge. Xenon lamps have been developed which provide a constant light (described as sunlight-plus-north-sky light) even when there are significant voltage changes. Thus, the lamps do not require voltage regulators. For a given wattage, xenon lamps have been found to deliver a greater light output. For example, an 800-watt xenon lamp will produce 2,000 lumens as compared with a 1,000-watt incandescent lamp that produces only about 200 lumens. Xenon also has found application in certain lasers. It has been found that xenon produces mild anesthesia, but cannot be used for surgery because the quantity required would cause asphyxiation. Xenon is used in bubble chambers, probes, and other applications where its high molecular weight is of advantage in the atomic energy field. Potentially, xenon is of interest as a gas for ion engines. The perxenates have been used as oxidizing agents in analytical chemistry. Xenon 133 and 135 are produced by neutron irradiation in air-cooled nuclear reactors. Xenon 133 has been found useful as a radioisotope in various studies.

XENOTOPIC. The fabric of a crystalline sedimentary rock in which the majority of the constituent crystals are anhedral. Fabric found in evaporites, chemically deposited cement, and recrystallized limestone or dolomite.

XI PARTICLE. A hyperson with a rest-mass energy of about 1318.4 MeV, an isospin quantum number $\frac{1}{2}$, an angular momentum spin quantum number $\frac{1}{2}$, and a strangeness quantum number 2. Symbol, Ξ.

X-RAY. In 1895, W. Roentgen of Würzburg, Germany discovered x-rays accidentally while experimenting with a Crookes tube. Roentgen observed the fluorescence of a barium platinocyanide screen that happened to lie near the tube and traced the effect to something that emanated from the spot where the cathode rays struck the tube wall. Putting the tube in a pasteboard box made no difference; so it was not light or ultraviolet radiation that caused the fluorescence. Investigation rapidly followed and relatively soon, x-rays were being used by surgeons to examine the bones of living people. X-ray photos are also used in industry. See Fig. 1.

It was soon found that x-rays arise wherever cathode rays encounter solids; that "targets" of high atomic weight yield more copious X-rays; and that the greater the speed of the cathode particles, the more penetrating, or the "harder" the X-rays are. Special tubes were designed for producing x-rays. The earlier tubes were of the Crookes type, depending on the conduction of ionized gas. Those most used now are thermionic, of the Coolidge type, with a hot-wire cathode operating in a high vacuum; a construction which permits the passage of very high-speed electrons under voltage control, the quantity of them, and the intensity of the resulting X-rays, being regulated by the filament temperature.

Early experiments indicated that x-rays are something essentially different from light, an erroneous conclusion based upon the failure to observe regular reflection, refraction, or diffraction. We now know that this failure was due to the extremely short wavelength of the rays, the range of which extends from the extreme ultraviolet into the gamma-ray region, that is, from 10^{-7} to 10^{-9} centimeter. It is also known that X-rays are produced: (1) when electrons, accelerated in a vacuum, strike a target and lose kinetic energy in passing through the strong electric fields surrounding the target nuclei, thus giving rise to bremsstrahlung and resulting in a continuous x-ray spectrum; and (2) by the transitions of atoms from higher energy states to K, L, ... energy states, thus giving rise to characteristic x-rays. The term x-rays is not used to refer to the characteristic radiation from an element of atomic number Z less than 10, since the wavelengths of such radiation exceed those in the x-ray range. However, every element has its characteristic X-ray spectrum, when used as a target, although according to the Duane and Hunt law the radiation also depends on the accelerating voltage.

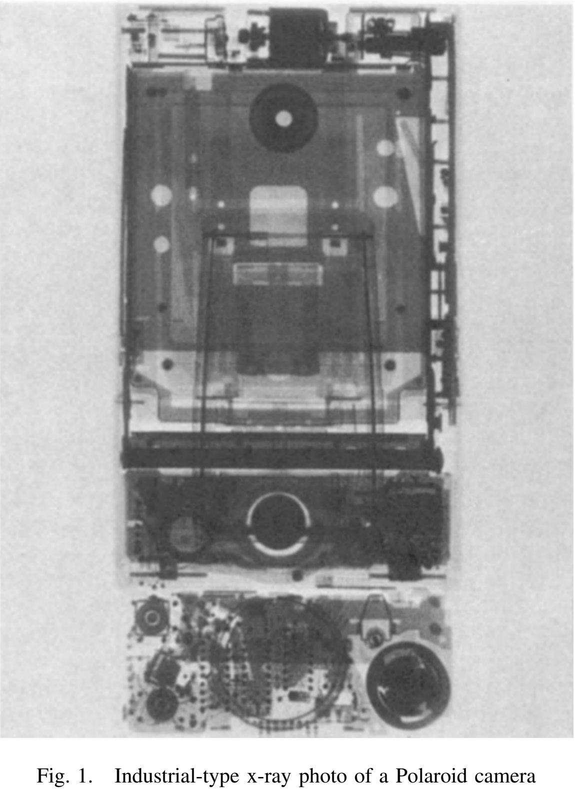

Fig. 1. Industrial-type x-ray photo of a Polaroid camera

There are three principal means of detecting x-rays: the fluorescent effect, the photographic effect, and the ionizing effect. The only method at first available for distinguishing radiation of different wavelengths was to measure their penetration or their absorption coefficient in various substances. The discovery of the X-ray diffraction or grating effect of crystals, by von Laue, Friedrich, and Knipping, in 1912, made it possible to analyze the rays and measure their wavelengths very much as light is studied with the spectroscope. When X-rays of given wavelength are incident upon a crystal turned in various directions, the layers of atoms, at certain angles of incidence, reflect wave trains in phase with each other which, if caught on a photographic plate, produce a "Laue pattern." While the matter is not as simple as in the case of light incident on a diffraction grating, it is nevertheless possible to interpret such patterns in somewhat the same way as a line spectrum, and to deduce the wavelength from it. A unit convenient for expressing X-ray wavelengths is the "X-unit," which is 10^{-11} centimeter or 0.001 angstrom. See also **X-Ray Analysis**.

X-RAY ANALYSIS. X-rays occupy that portion of the electromagnetic spectrum between 0.01 and 100 angstroms (Å). Their range of approximate quantum energy is from 2×10^{-6} to 2×10^{-10} erg, or from 106 to 100 eV. Important X-ray analytical methods are based upon: (1) fluorescence; (2) emission; (3) absorption; and (4) diffraction. These methods are used qualitatively and quantitatively to determine the element content of complex mixtures and to determine exactly the atomic arrangement and spacings of crystalline materials. See also **Ion Microprobe Mass Analyzer**.

Source of X-rays

X-rays are emitted by atoms that are bombarded with energetic electrons. This results from two separate effects: (1) deceleration of high-speed electrons as they pass through matter, and (2) ionization of individual atoms which abruptly stop the electrons. The first effect results in a continuous-type spectrum; the second effect results in characteristic line spectra.

Continuous Spectrum

The bulk of X-radiation arising from electron bombardment is the continuous spectrum. If an individual electron is abruptly decelerated, but not necessarily stopped, in passing through or near the electric field of a target atom, the electron will lose some energy DE, which appears as an X-ray photon of frequency $v = \Delta E/h$, where h is Planck's constant. An electron may experience several such decelerations before it is finally stopped, emitting x-ray photons of widely different energy and wavelength. A few electrons will be stopped in a single process, losing their entire energy and emitting an X-ray photon having the exact energy of the incident electron.

X-Ray Spectral Lines

These result when the incident electrons knock orbital electrons out of an atom. If an ejected electron is from one of the inner orbits of the

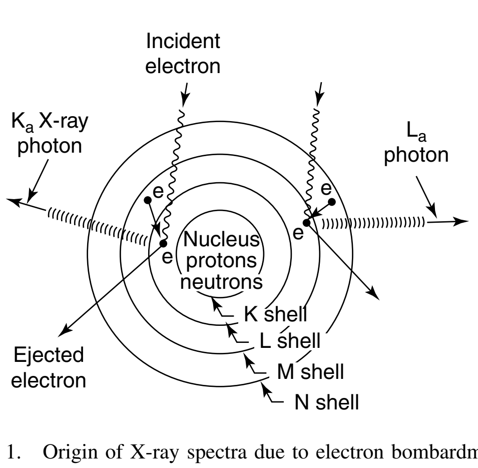

Fig. 1. Origin of X-ray spectra due to electron bombardment

atom (Fig. 1), an electron from an outer shell will fall to the inner orbit to fill the vacancy. The decrease in potential energy of this electron in approaching the nucleus results in the emission of an X-ray photon having an energy exactly equal to that lost by the electron. The wavelength λ for such photons is related to ΔE by $\lambda = ch/\Delta E$, where c is the velocity of electromagnetic energy and h is Planck's constant. Because the energy of orbital electrons is quantized, the X-ray photons can have only certain definite wavelengths which are characteristic of the atom. This situation is somewhat analogous to the more familiar ultraviolet and visible-emission spectra of materials, the difference being that the optical spectra are the result of electron transitions between energy levels of just the outermost electrons of the atoms.

X-rays resulting from an electron transition filling an electron vacancy in the innermost shell of an atom are known as K x-rays or K lines; those from the L shell are known as L lines, and so on.

Generation of X-rays

An important component in an X-ray analytical device is an x-radiation generator. A high-vacuum Coolidge type tube, wherein electrons are emitted from a heated tungsten filament and accelerated by a high voltage to an anode (target) is a common source of x-rays. See Fig. 2.

A wide variety of tubes is available. All high-power (high-current) commercial tubes employ a water-cooled anode. Tubes of this type have been built with ratings up to 10 kilowatts.

Detection of X-rays

Detectors include (1) Geiger-Mueller tube, (2) ionization chambers, (3) scintillation counters, (4) proportional counter, (5) electron-multiplier tubes, and (6) nondispersive detectors using cooled lithium-drifted Si detectors. See Fig. 3.

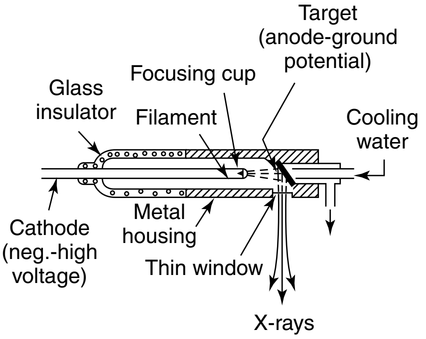

Fig. 2. High-voltage, high-vacuum X-ray tube

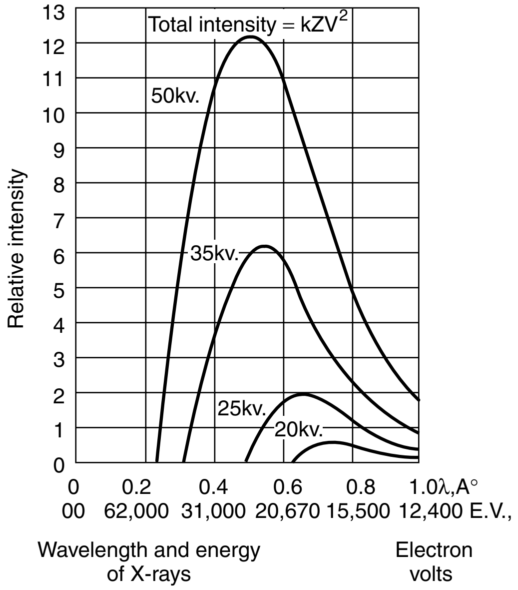

Fig. 3. Continuous X-ray spectrum of tungsten ($Z = 74$) at various tube voltages

X-ray Crystallography

X-rays penetrating below the surface of crystalline materials are scattered by the individual parallel layers of atoms; each atomic layer acts as a new, although weak, source of X-rays. To be reinforced in a given direction at an angle θ (Fig. 4), the spacing d between crystal planes must be rigorously related to the wavelength of the radiation. At a given angle, X-rays of one definite wavelength will be constructively reinforced. These variables are related by Bragg's law.

$$n\lambda = 2d \sin\theta$$

where n is an integer. Note that θ is measured relative to the crystal face rather than to the perpendicular.

In addition to fulfilling this wavelength requirement, the energy will be diffracted only at an angle equal to the angle of the incident x-rays, independent of wavelength; otherwise, destructive interference is possible, and the "reflected" energy is negligible.

X-Ray Analyzer, Electron-Microprobe

Advantages of this analytical instrument include: (1) analysis can be confined to very small (microsamples) amounts of materials; (2) the particular material to be analyzed need not be physically separated from its surrounding materials, as is often required with many analytical methods; and (3) through the development of associated instrumentation, diagnostic techniques, and information displays, the method can be quite fast. Limits of detection in solid solution are from approximately 0.005 to 0.5%, depending upon the elements and sample matrixes involved. See Fig. 5. Concentrations as low as 10^{-16} gram may be measured.

Mainly used for metallurgical studies, nonmetallics also may be analyzed when samples are properly prepared. Biological applications include tooth and bone samples, cytochemical problems and staining techniques, physiochemical problems, and studies in pathology. Relative weight-fraction-detection limits for most elements in biological specimens are in the general range of 0.01 to 0.10%. Electronics industry applications include studies of diffusion phenomena, electrical-contact surfaces, interfaces on transistors, and microcircuitry analysis.

As shown by Fig. 6, electrons from an electron gun are directed to the sample through an electron optical system. Once the electron beam

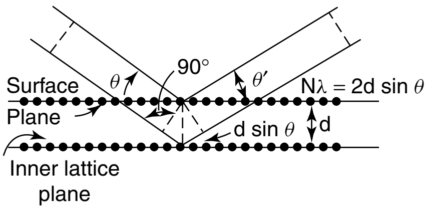

Fig. 4. Reflection of X-rays from internal crystal plane

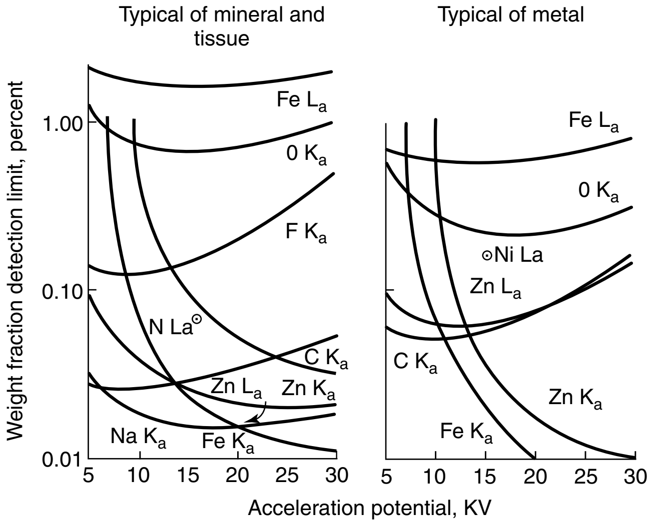

Fig. 5. Typical weight-fraction detecting limits of electron microprobe X-ray analyzer

strikes the sample, a number of signal sources are activated, including (1) high-energy backscattered electrons, (2) low-energy secondary electrons, (3) cathodoluminescence, and (4) x-rays. Some heat also is generated within the sample. Volume d_3 of the specimen is that *volume from which X-rays are emitted*.

The X-rays produced may be detected nondispersively by a proportional counter whose output may be separated as a function of energy by a pulse-height analysis system into the various wavelength components. Better detection sensitivities, however, can be obtained through the use of a fully focusing diffracting-crystal spectrometer in conjunction with a proportional detector and the necessary pulse-height analyzer. As shown by Fig. 7, the necessary condition for fully focusing optics is to have the x-ray source, the crystal, and the detector slit all placed on a common circle. This geometry requires that the diffracting-crystal planes be bent to the diameter of the Rowland circle.

Spherical aberration at the detector slit is minimized by further grinding the crystal surface to fit the radius of the Rowland circle. With the resultant

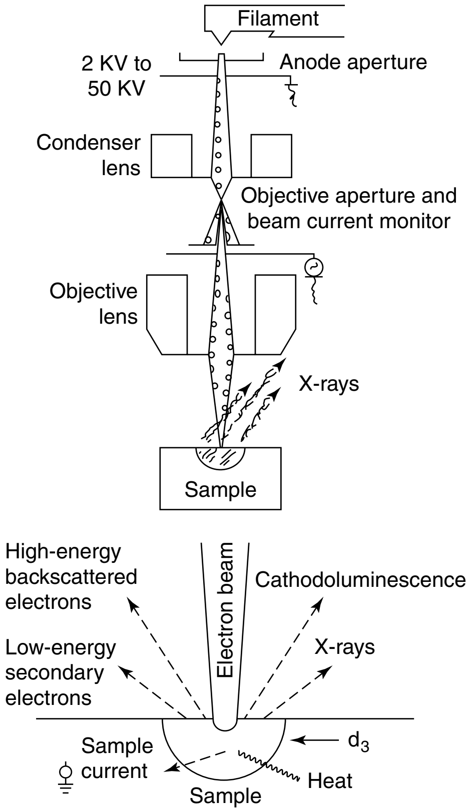

Fig. 6. Electron gun and probe-forming lens system of an integrated electron probe

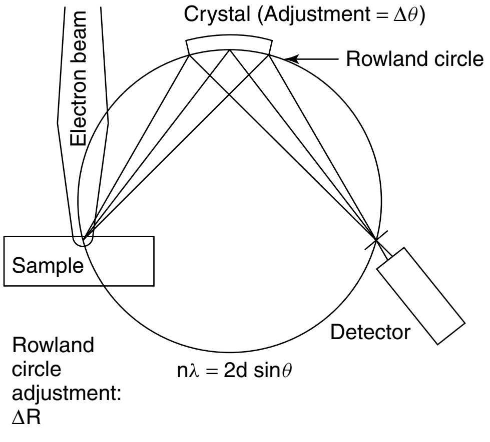

Fig. 7. Geometry of a fully focusing diffracting-crystal spectrometer

Johansson optics, the crystal radius is fixed, and the 2θ range of the spectrometer is scanned by moving the crystal radially away from the source and, at the same time, rotating it into the detector to achieve a true focus throughout the spectrometer range. X-rays particularly of a wavelength greater than 2 Å, and electrons are highly absorbed in an air atmosphere. Thus, the spectrometer must be enclosed in a vacuum of the order of 10^{-5} torr. The present wavelength range of interest extends from approximately 1 to 100 Å. Diffracting crystals to cover this range must provide broad wavelength coverage, high diffraction efficiencies for high peak-count intensities, good resolution, and good resulting peak-to-background ratios. Crystals that meet these objectives include lithium fluoride, ammonium dihydrogen phosphate (ADP), ethylenediamine *d*-tartrate. (EDT), quartz, and sodium chloride.

Detectors

Of the three commonly used X-ray detectors—(1) Geiger counter, (2) scintillation counter, and (3) proportional counter—the latter is used most frequently for electron-probe microanalysis. In the wavelengths from 1 to 10 Å, sealed proportional counters may be used. For longer-wavelength analysis—in the range from 10 to 93 Å—the thinnest possible detector window is required to limit spectral attenuation. Nitrocellulose windows have proved successful. Nondispersive detection systems using cooled Li-drifted Si are also applicable.

An *optical microscope* is required in the system to provide the analyst with a means of reference to identify various sample areas for analysis. Sample stages may hold single or multiple samples and are provided with means for moving the sample in x, y, and z planes without breaking the system vacuum. After the point of interest is located on the specimen, the data may be read out in a number of ways: (1) quantitative and semiquantitative information may be obtained by processing the x-ray detector signal through a rate meter to a strip-chart or X–Y recorder; (2) scaler systems also provide direct readout of quantitative data integration; and (3) for operational convenience, a data translator and typewriter or teletype printout system may be connected directly to record digital-counter information as hard copy.

X-ray Fluorescence Analysis

One of several types of spectrochemical techniques now used for laboratory analysis. The method is nondestructive. The characteristic X-ray spectrum of each element bears a simple direct relationship to the atomic number. The relation of the wavelength λ to the atomic number Z is

$$\frac{1}{\lambda} a Z^2 (\text{Mosley's law})$$

Since the X-ray spectral lines come from the inner electrons of the atoms, the lines are not related to the chemical properties of the elements or to the compounds in which they may reside. Because the characteristics of the X-ray spectra are associated with energies released through transitions of electrons within the inner shells of the atom, the spectra are simple. Most practical X-ray fluorescence analysis involves the detection of radiation release through electron transitions from outer shells to the K shell (K spectra), outer shells to the L shell (L spectra) and, in very few cases, from outer shells to the M shell (M spectra).

The simplest form of energy source available for commercial instrumentation is that obtained from an X-ray tube. For samples containing predominantly low-atomic-number elements, as in cement raw mix, the most efficient excitation is accomplished by using an X-ray tube target material of relatively low atomic number, such as chromium. Elements having higher atomic numbers are most effectively excited by high-atomic-number targets, such as tungsten or platinum. An optimum target material is rhodium for the analysis of a broad range of elements. The X-ray tube irradiates the sample, which in turn emits characteristic fluorescent radiation of its atoms.

Once X-ray fluorescence is produced from the sample by means of an X-ray tube, appropriate components of the instrument (Fig. 8) separate this radiation into its characteristic wavelengths, detect the energy emitted from each excited atom, and produce a signal that is representative of the number of atoms (concentration) of the elements in the sample. Typical excitation conditions (x-ray tube) are 50 kilovolts, 35 milliamperes. Bragg's law of X-ray diffraction is satisfied by the condition $N\lambda = 2d \sin q$, where λ is the wavelength and θ is the angle of incidence and diffraction of X-rays from a crystal whose lattice spacing is defined by d and N, the order of

harmonic of the diffraction. For almost all fluorescence analysis, $N = 1$. The usable x-ray spectrum normally extends from 0.1 to about 20 Å. A helium or vacuum path is required for x-ray analysis of elements with atomic numbers lower than $Z \cong 24$ (wavelengths longer than 2.3 Å).

Instrumentation can provide for simultaneous elemental analysis using fixed, preselected X-ray detection channels and scanners or a goniometer to provide one or more channels that can be tuned to a wide wavelength coverage. Up to 30 monochromator positions are possible. Typical crystal materials covering the practical wavelength range of 1 to 20 Å are lithium fluoride, silicon oxide, sodium chloride, EDT, and ADP. Optimum analytical data for the elements of interest are obtained by using fully focusing Johansson curved and ground crystals.

An optical diagram of a Johansson curved-crystal spectrometer is given in Fig. 9. Each spectrometer of an x-ray quantometer may be equipped with optimum crystal-detector combinations for specific determinations in a wide variety of matrixes, including steel, aluminum, copper-base materials, ores, cement, and slags—in both liquid and solid states.

The diffracted X-radiation is detected by Geiger, proportional, or semiproportional detectors. See Fig. 10. The detector of each monochromator generates pulses, which are a measure of the intensity of radiation of each wavelength. The pulses are filtered through a discriminator in order to avoid undesired interferences. Pulses shrinking due to an increase of frequency of pulses is automatically compensated. Collected pulses are transferred to a computer for processing and output. See Fig. 11.

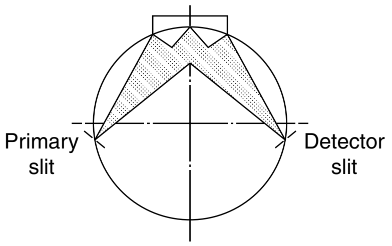

Fig. 9. Optical diagram of Johansson curved-crystal spectrometer

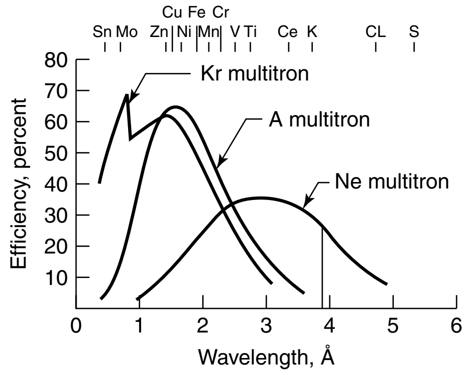

Fig. 10. Relative efficiency of X-radiation detectors

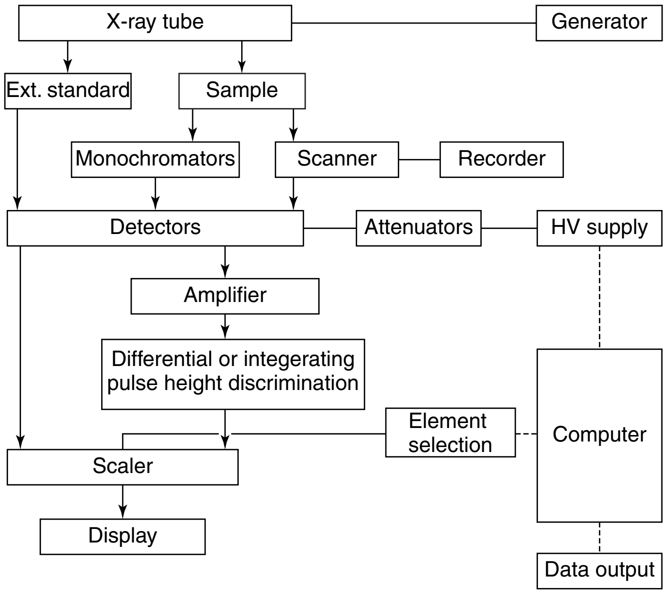

Fig. 11. System configuration of X-ray fluorescence analyzer

The transition from laboratory to automated instrument to achieve high-speed continuous analysis of dry or wet materials primarily involves the sample-handling and presentation hardware.

Limits of detectability for the desired elemental analyses vary depending upon the matrix, elements, methods of sample preparation, and quality of instrumentation applied. Generally, these are on the order of 1 to 100 parts per million. The limit of detectability, however, is only one criterion in evaluating methods of analysis. The time of analysis is important, particularly in production and process control laboratories. In multi-element spectrometers, it is possible to perform as many as 30 simultaneous elemental determinations in from 20 to 120 seconds, depending upon the material being analyzed.

X-RAY SCAN AND OTHER MEDICAL IMAGERY. Introduction of computerized axial tomography in the form of the X-ray cat scanner (CAT) was a major event in the history of diagnostic medicine. The technology is also referred simply as computerized tomography (CT).

Tomography as a technique of X-ray photography by which a single selected plane is photographed, with the outline of structures in other planes eliminated, has been known for many years. X-rays lose energy in direct proportion to the density of the structure through which they pass. Thus dense structures of the body, such as bone, absorb much of the X-radiation and therefore in a traditional X-ray negative appear as light images—because less radiation has reached the film. The CAT scanner utilizes this same general principle (more or less energy absorbed, depending upon density of intervening tissue). But, instead

of exposing a single X-ray film, or taking a series of single exposures from different angles and then comparing these in an attempt to create some semblance of the object in three dimensions, the CAT scanner indicates the exact amount of energy absorbed by the object from many different angles—so that the final image as seen by the radiologist is based upon a composite of contiguous one-millimeter cross sections. Film is replaced by electronic X-radiation detectors and the processing of so much information obtained in such a short time span is processed by a computer. A rapid rate of calculation is needed to measure tissue density, requiring the solution of about one-half million equations every few minutes.

The CAT scanner has been likened to a large doughnut that houses x-ray tube and detectors. The doughnut is positioned around the part of the patient to be examined. As the patient lies on a table, the doughnut, housed in a large gantry, rotates, creating images as it turns. When the X-ray beam passes through the body, it strikes a detector in which calcium fluoride crystals scintillate (flash light). These scintillations are transmitted to a computer as electric signals. While the computer processes the information, registering it on a cathode ray tube, the doughnut rotates a few degrees and repeats the process until it has completed a 180-degree arc around the patient. The scanner forms a grid of readings with innumerable X-rays creating a matrix of nearly 100,000 intersections as they enter from various angles. The average amount of X-radiation absorbed by a patient during a CAT scan is estimated to be about one-fifth that absorbed in X-ray exposures in a typical executive physical given by many clinics and hospitals over 40 years of age.

The result is an X-ray image that gives the illusion of three dimensionality. Because the CAT beam is rotated around the body, it can image organs that overlap and are therefore obscured under conventional x-rays or radiograms. By using several hundred X-ray detectors to produce one exposure, the CAT is an order of magnitude more sensitive to slight gradations in density than radiographs, which frequently do not allow the practitioner to distinguish between tissues of approximately the same density.

Prior to the CAT scanner, normal X-ray photographs of the brain tended to be blurred beyond recognition by the skull. Since the first application of the CAT scanner to brain imaging in 1972, the instrument has come to be considered an indispensable neurophysiological tool. Prior to the availability of the CAT technique, an image of the brain's complex vascular system was obtainable only by means of an angiogram or arteriogram. Patients were given an injection of a dye directed to a specific site. In the diagnosis of some brain diseases, it was necessary to make a pneumoencephalogram ("air scan"), in which gas was injected into the lower spine and flowed upward to fill and outline brain cavities prior to x-ray procedures. These were both dangerous and painful procedures and required up to 2 or 3 days of hospitalization just for diagnostic purposes. The CAT can provide a detailed cross section of the brain in as brief a span as five minutes. Air scans can be eliminated and the need for angiograms has been sharply reduced. Rapid, usually accurate diagnosis of brain disorders and injuries has saved lives by reducing exploratory surgery and by greatly shortening delays in commencing treatment.

The image of an 80–90% underexposed medical radiograph can be increased to readable density and contrast by autoradiographic image intensification. The technique consists of combining the image silver of the radiograph with a radioactive compound, thiourea labeled with sulfur-35, and then making an autoradiograph from the activated negative.

Minimizing the X-ray dose received by patients during medical examinations and maximizing the quality of the radiographs are subjects of concern to the medical profession and the public. Some conflict is inherent in the two objectives because higher quality radiographs, i.e., those which convey more information to the physician, usually require higher exposure levels. Recent gains in quality or exposure reductions, or both, are due to developments, such as computer processing, electrostatic imaging systems, improvements in intensifying screens, and scatter rejection techniques.

Radiographs which are normally classified as "badly underexposed" actually contain most of the information which was intended to be recorded by the original exposure. Autoradiographic intensification effectively retrieves this information by increasing the image density and contrast to readable levels. The intensification occurs on an autoradiograph made from the underexposed film after the original image silver has been chemically combined with a radioactive isotope.

Other Photon Imaging Techniques

Since introduction of X-ray CAT scan technology, other photon imaging approaches have been developed. These concepts augment and, in some instances, are alternatives to the X-ray CAT scan. The more recent developments include positron emission tomography, K-edge dichromography, the use of synchrotron radiation, angiographic imaging, and nuclear magnetic resonance imaging. The latter topic is described in the article on **Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI)**. The recent use of synchrotron radiation is described under **Particles (Subatomic)**.

Positron Emission Tomography (PET). In PET, image construction is based on the location and intensity of gamma rays emitted in the region of a *neutron-poor* isotope. Planar images formed by computer PET result from the attenuation coefficients of the tissues that intercept a transmitted x-ray beam. Neutron-poor isotopes undergo radioactive decay by the process $P^+ \rightarrow N + e^+ + v$, where P^+ is a nuclear proton, N is a neutron, e^+ is a positron, and v is a neutrino. A neutron-poor isotope, such as ^{11}C will undergo beta decay, in which a proton becomes a neutron and a positron and a neutrino are ejected from the nucleus. Within a short distance, the positron encounters an electron, upon which the two annihilate each other and give rise to a pair of gamma-ray photons that depart at an angle of about 180°, each carrying an energy of 0.511 MeV.

The major isotopes used in PET are ^{15}O (half-life = 20 min), ^{13}N (half-life = 10 min), ^{11}C (half-life = 20 min), and ^{18}F (half-life = 110 min). Half-life spans are approximate. The foregoing isotopes are produced by a nearby cyclotron. They are either administered promptly, or are rapidly incorporated into appropriate molecules, such as metabolic substrates, substrate analogues, or drugs, which are then administered. Minicyclotrons for generating radionuclides are becoming available as of the late 1980s.

As pointed out by Ter-Pogossian and Brownell, the gamma photons derived from the decay of the isotopes within the patient's body are sensed by a circumferential array of collimated detectors, the circuitry of which is designed so that opposite members of the ring are coupled. A signal is recorded only when both members of the detector pair sense coincidental photons. By using a slight time difference in the activation of the detectors, one can locate the source of the photons on the basis of time-of-flight differences from an eccentrically positioned emitter. Data are fed into a computer, which generates the image based on location and source intensity. Tissue attenuation is taken into account. Spatial resolution is about 0.5 cm. Only minute amounts of tracers are needed. The radiation dose is small.

PET is particularly adapted to kinetic analysis of physiologic and biochemical events, including blood volume, blood flow, and consumption of oxygen and substrates. Some applications of PET include the following. (1) Identifying uptake of the glucose analogue ^{18}F-fluorodeoxyglucose in various regions of the brain. As pointed out by Mazziotta and Reivich, the laterality of neurologic responses to auditory stimulation has been correlated in this way. Visual stimuli of increasing complexity have been observed to produce symmetric increases in uptake in the primary and associative visual cortices, with a correlation of visual pathway abnormalities with neurologic findings. (2) Studies of Alzheimer's disease patients indicate dysfunction in temporal-parietal regions and in the structures near the third ventricle, as reported by de Leon and Friedland. (3) Studies of schizophrenic patients have suggested subtle local blood flow and metabolic changes. (4) Measurements of altered blood flow, oxygen utilization, and oxygen extraction fraction have been made in patients who have undergone a recent cerebral infarction, as noted by Baron. (5) A study of an adolescent who had cerebral vasculitis due to systemic lupus erythematosus showed local changes, when revealed by PET, that correspond with electroencephalographic findings. After remission, the PET abnormalities vanished. (6) Some patients with brain tumors have been examined by PET. In a very large percentage of cases, a positive correlation between tumor glycolysis and tumor histologic grade has been observed by PET (as noted by DeLaPaz). (7) Kuhl reports that in some patients with epilepsy, during interictal periods, the involved zones are hypometabolic. (8) In Duchenne's muscular dystrophy, biochemical abnormalities associated with the characteristic involvement of the posterolateral region of the left ventricle have been identified by PET. There are many other examples of the contributions of PET to patient diagnosis and biochemical research.

Digital Subtraction Angiography. Routine roentgenograms do not reveal vascular structures because blood vessels and surrounding soft tissues attenuate x-ray beams in the same way, thus not revealing any distinction between the two. Conventional arteriography requires high concentrations of iodine-containing contrast agents to be injected directly into an artery. The attenuation of the x-rays through Compton and photoelectric interactions with iodine provides the required contrast between vessels and surrounding tissues. An alternative technique known as digital subtraction angiography (DSA) requires considerably lower concentrations of contrast agents. DSA is now widely practiced by giving a peripheral or central intravenous injection of contrast materials. Most often, the agents will be administered by a pump-driven device. In this method, an x-ray image is acquired on an area detector, such as a fluoroscope screen, or on a scanning line detector. Data then are digitized, amplified, and transferred to a computer.

An optimal approach to DSA angiography is that of using monochromatic x-ray beams at energy levels just above and just below the K-shell absorption edge of iodine. Image data above the K-edge include information arising from Compton and photoelectric interactions of x-ray beams with iodine and with atoms in the molecules of the soft tissues and bones of the body. The image recorded just below the K-edge includes virtually the same attenuation data except for additional information that arises from photoelectric absorption by K-shell electrons in iodine atoms. The logarithmic subtraction of the two images almost totally suppresses signals arising from soft tissue and bone, as observed by Rubenstein and Hughes.

XYLENE. [CAS: 1330-20-7]. $C_6H_4(CH_3)_2$, formula weight 106.16. There are three xylenes, ortho-, meta-, and para-xylene. Sometimes referred to as dimethylbenzenes, the xylenes have the following key physical properties:

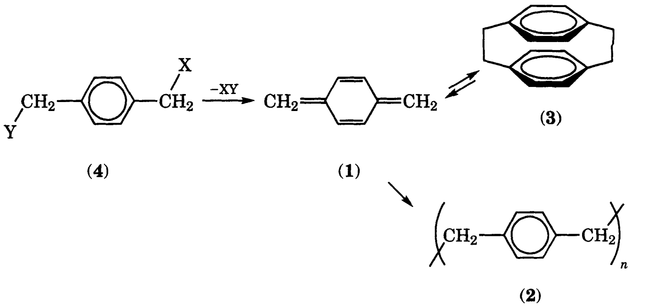
o-Xylene	mp −25°C	bp 144°C	sp gr 0.881
m-Xylene	−47.4°C	139°C	0.867
p-Xylene	13.2°C	138.5°C	0.861

All of these compounds are insoluble in H_2O, soluble in alcohol, and *o*-xylene and *m*-xylene are miscible in all proportions with ether; *p*-xylene is very soluble in ether.

The xylenes are very high-tonnage industrial chemicals and are raw materials or intermediate materials for numerous synthetic fibers, resins, and plastics. See also **Xylene Polymers**. A large amount of *p*-xylene goes into polyester fiber production, while substantial quantities of *o*-xylene are consumed by the manufacture of phthalic anhydride. The prime source of xylenes are petroleum refinery reformate streams in conjunction with benzene and toluene extraction. The xylenes occur mixed in these streams.

When naphtha or naphthenic gasoline fractions are catalytically reformed, they usually yield a C_8 aromatics stream that is comprised of mixed xylenes and ethylbenzene. It is possible to separate the ethylbenzene and *o*-xylene by fractionation. It is uneconomic to separate the *m*- and *p*-xylenes in this manner because of the closeness of their boiling points. To accomplish the separation, a Werner-type complex for selective absorption of *p*-xylene from the feed mixture may be used. Or, because of the widely different freezing points of the two xylene isomers, a process of fractional crystallization may be used. To boost the *p*-xylene yield, the filtrate from the crystallization step can be catalytically isomerized.

XYLENE POLYMERS. In a process capable of producing pinhole-free coatings of outstanding conformality and thickness uniformity through the unique chemistry of *p*-xylylene (PX) (**1**), a substrate is exposed to a controlled atmosphere of pure gaseous monomer. The coating process is best described as a vapor deposition polymerization (VDP). The monomer molecule is thermally stable, but kinetically very reactive toward polymerization with other molecules of its kind. Although it is stable as a rarified gas, upon condensation it polymerizes spontaneously to produce a coating of high molecular weight, linear poly(*p*-xylylene) PPX) (**2**).



In the commercial Gorham process, PX is generated by the thermal cleavage of its stable dimer, *cyclo*-di-*p*-xylylene (DPX), a [2.2]paracyclophane (**3**). In many instances, substituents attached to the paracyclophane framework are carried through the process unchanged, ultimately becoming substituents of the polymer in the coating.

The PPXs formed as coatings in the Gorham process are referred to generically as the parylenes.

The parylene process has certain similarities with vacuum metallizing. The principal distinction is that truly conformal parylene coatings are deposited even on complex, three-dimensional substrates, such as on sharp points and in hidden or recessed areas. Vacuum metallizing, on the other hand, is a line-of-sight coating technology.

The *p*-xylylene species plays a central role in the coating process itself as well as in the making of the dimers which are used as feed-stocks for the coating process. Polymers and dimers have both been made from precursor *p*-xylene compounds (**4**) featuring a variety of X and Y leaving groups.

Gorham Process Monomers

The eight-carbon monomer PX is generated in the first stage of the parylene process by heating gaseous dimer as it passes through a high temperature zone.

Chemical Evidence for PX Monomer. Establishing early on that PX is indeed the pyrolysis product, rather than the molecule formed by breaking only one of the original dibenzyl bonds, the dimer diradical (**5**), proved to be an important development.

(**5**)

When the pyrolysis gases are quenched with a molar excess of iodine vapor, a yield of greater than 50% *p*-xylylene diiodide is recovered. The observation of this effect offered the first direct chemical support for the idea that DPX pyrolysis results in PX (**1**).

Monomer Properties. Despite difficulties involved in studying it owing to its great reactivity, a great deal is known about the structure of the parylene. The eight-carbon framework of the monomer PX is planar. The molecule is diamagnetic, i.e., all electron spins are paired in the ground state (spectroscopically, a singlet). The PX molecule is a conjugated tetra

olefin whose particular arrangement gives it extreme reactivity at its end carbons (**6**).

(**6**)

A particularly useful property of the PX monomer is its enthalpy of formation. Using a semiempirical molecular orbital technique, the heat of formation of *p*-xylylene has been computed to be 234.8 kJ/mol (56.1 kcal/mol).

Successful p-Xylylene VDP Monomers. Within the limits mentioned above, it is frequently possible, and often desirable, to modify the *p*-xylylene monomer by attaching to it certain substituents. Limitations on such modifications lie in the three areas: reactivity, performance in the coater (deposition equipment) and cost.

Other, Related Processes

VDP processes using means other than the pyrolytic cleavage of DPX (Gorham process) to generate the reactive monomer are also known, although none are practiced commercially at present.

Dimer

In contrast to the extreme reactivity of the monomeric PX (**1**) generated from it, the dimer DPX (**3**) feedstock for the parylene process is an exceptionally stable compound. At present only three dimers are commercially available: DPXN, DPXC, and DPXD, which give rise to Parylene N, Parylene C, and Parylene D, respectively.

The unsubstituted C-16 hydrocarbon, [2.2]paracyclophane (**3**), is DPXN. Both DPXC and DPXD are prepared from DPXN by aromatic chlorination and differ only in the extent of chlorination; DPXC has an average of one chlorine atom per aromatic ring and DPXD has an average of two.

Manufacture. For the commercial production of DPXN (di-*p*-xylylene) (**3**), two principal synthetic routes have been used: the direct pyrolysis of *p*-xylene (**4**, X = Y = H) and the 1,6-Hofmann elimination of ammonium (HNR_3^+) from a quaternary ammonium hydroxide (**4**, X = H, Y = NR_3^+). Most of the routes to DPX share a common strategy: PX is generated at a controlled rate in a dilute medium, so that its conversion to dimer is favored over the conversion to polymer.

Purification. Unsubstituted di-*p*-xylylene (DPXN) is readily purified by recrystallization from xylene. It is a colorless, highly crystalline solid. The principal impurity is polymer, which is insoluble in the recrystallization solvent and easily removed by hot filtration. In purifying DPXC and DPXD, care is taken not to disturb the homologue composition, so that product uniformity is maintained.

Properties. The DPXs are all crystalline solids; melting points and densities are given in Table 1. Their solubility in aromatic hydrocarbons is limited.

The structure of DPXN was determined from x-ray diffraction studies. There is considerable strain energy in the buckled aromatic rings and distorted bond angles. The release of this strain energy is the principal reason for success in the preparation of monomer in the parylene process.

Polymer

The linear polymer of PX, poly(*p*-xylylene) (PPX) (**2**), is formed as a VDP coating in the parylene process. The energetics of the polymerization set it apart from all other known polymerizations and enable it to proceed as a vapor deposition polymerization.

Thermodynamic Considerations. On the basis of the value for the enthalpy of formation of *p*-xylylene, the enthalpy of polymerization, can be estimated.

TABLE 1. PROPERTIES OF PARYLENE DIMERS

DPXC	140–160[b]	1.30
DPXD	170–195[b]	1.45

[a] Decomposes.
[b] Mixture of homologues and their isomers.

Polymerization Mechanism. The physical processes of condensation and diffusion must be considered along with the *p*-xylylene polymerization chemistry for a proper understanding of what happens microscopically during vapor deposition polymerization. These processes point to an important distinction between VDP and vacuum metallization, i.e., that in the latter, adsorption is followed by a surface reorganization of the existing deposited material, and diffusion of incoming species through the bulk is nonexistent. In most parylene depositions, a coating forms from gaseous monomer under steady-state conditions.

The monomer is consumed by two chemical reactions: initiation, in which new polymer molecules are generated, and propagation, in which existing polymer molecules are extended to higher molecular weight. In steady-state VDP, both reactions proceed continuously inside polymeric coating, in the reaction zone just behind the growth interface.

The concentration of monomer within the coating decreases approximately exponentially with distance from the growth interface. With this decrease in monomer concentration, the rates of initiation and propagation reactions also decrease. Moving back into the polymer from the growth interface, through the reaction zone where polymer is being manufactured, a region in which the polymer formation is essentially complete is gradually entered. Under conditions prevailing during a typical deposition, the characteristic depth of the reaction zone is a few hundred nanometers, and the maximum concentration of monomer, i.e., the concentration at the growth interface, is of the order of a few tenths percent by weight. Thus the parylene polymerization takes place just behind the growth interface in a medium that is best described as a slightly swollen, solid polymer.

During the vapor deposition process, the polymer chain ends remain truly alive, ceasing to grow only when they are so far from the growth interface that fresh monomer can no longer reach them. No specific termination chemistry is needed.

Polymer Properties. The single most important feature of the parylenes, that feature which dominates the decision for their use in any specific situation, is the vapor deposition polymerization (VDP) process by which they are applied. VDP provides the room temperature coating process and produces the films of uniform thickness, having excellent thickness control, conformality, and purity. The engineering properties of commercial parylenes once they have been formed are given in Table 2.

The most important mode of degradation for parylenes is oxidative chain scission. Oxidative degradation limits the use of parylenes at elevated temperatures in many common applications. Conventional antioxidants, incorporated during or after VDP, can extend the life of the parylenes at elevated temperatures.

The oxidation of parylene appears to be enhanced by ultraviolet radiation.

The bulk barrier properties of parylenes are among the best of organic polymeric coatings.

The parylenes do not absorb visible light, and absorb only at the shorter wavelength, high energy end of the ultraviolet range. Films and coatings are colorless in the visible, becoming opaque to sufficiently short wavelength uv light.

The crystallinity of the parylenes determines two of their most important practical characteristics: mechanical strength at elevated temperatures and solvent resistance. The crystallinity of parylenes is confined to small-submicrometer domains that are randomly dispersed throughout an amorphous continuum. Because the crystalline domains are much more resistant to permeation than the amorphous phase, they retain their reinforcing structural role even in the presence of permeants in the amorphous phase, thus giving the parylenes their resistance to solvent attack.

At temperatures below the melting of the crystallites, the parylenes resist all attempts to dissolve them.

Applications

Because the parylenes are generally insoluble in most solvents, even at elevated temperatures, they cannot be used as solvent-based coatings; neither can they be cast as films nor spun as fibers from solution. Because of their high crystalline melting points, melt-working (molding, extrusion, calendering, etc.) is also difficult. Yet it is often just these features of solvent resistance and high temperature mechanical strength that constitute the advantages of PPX materials.

The most important application of parylenes is as a conformal coating for printed wiring assemblies. These coatings provide excellent chemical resistance, and resistance to fungal attack. In addition, they exhibit stable dielectric properties over a wide range of temperatures.

The use of parylenes as a hybrid circuit coating is based on much the same rationale as its use in circuit boards. A significant distinction lies in obtaining adhesion to the ceramic substrate material, the success of which determines the eventual performance of the coated part. Adhesion to the which must be achieved using adhesion promoters, such as the organosilanes.

Parylenes are superior candidates for dielectrics in high quality capacitors. Their dielectric constant and loss remain constant over a wide temperature range. The thermistor sensing probe of a disposable bathythermograph is coated with parylene. This instrument is used to chart the ocean water temperature as a function of depth.

Parylene is used in the manufacture of high quality miniature stepping motors, such as those used in wristwatches, and as a coating for the ferrite cores of pulse transformers, magnetic tape-recording heads, and miniature inductors.

Parylene's use in the medical field is linked to electronics. For example, as a protective conformal coating on pacemaker circuitry.

As books age, the paper of their pages becomes brittle. A relatively thin coating of parylene can make these embrittled pages stronger.

By separating the coating from the substrate after deposition, the unique coating features of parylenes, especially continuity and thickness control and uniformity, can be imparted to a freestanding film. Applications include optical beam splitters, a window for a micrometeoroid detector, a detector cathode for an x-ray streak camera, and windows for x-ray proportional counters.

Parylenes can be used for contamination control, that is, securing small particles to prevent them from damaging a surface in a sealed unit; barrier coating; coating for corrosion control; and as dry lubricants.

Health and Safety

Provided the vacuum pump exhaust is appropriately vented and suitable caution is observed in cleaning out the cold trap, the VDP parylene process has an inherently low potential for operator contact with hazardous chemicals. Before using the process chemicals, operators must read and understand the current Material Safety Data Sheets, which are available from the manufacturers.

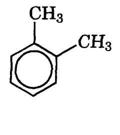
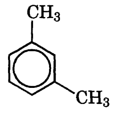
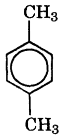
XYLENES AND ETHYLBENZENE. Xylenes and ethylbenzene (EB) are C_8 aromatic isomers having the molecular formula C_8H_{10}. The xylenes consist of three isomers: *o*-xylene (OX), *m*-xylene (MX), and *p*-xylene (PX). These differ in the positions of the two methyl groups on the benzene ring. The molecular structures are shown below.



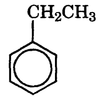
o-xylene (OX)



m-xylene (MX)



p-xylene (PX)



ethylbenzene (EB)

Sources and Uses

The term mixed xylenes describes a mixture containing the three xylene isomers and usually EB. Commercial sources of mixed xylenes include catalytic reformate, pyrolysis gasoline, toluene disproportionation product, and coke-oven light oil. Ethylbenzene is present in all of these sources except toluene disproportionation product. Catalytic reformate is the product obtained from catalytic reforming processes.

Pyrolysis gasoline is a by-product of steam cracking of hydrocarbon feeds in ethylene. Coke over light oil is a by product of the manufacture of coke for the steel industry.

Properties

Because of their similar molecular structures, the three xylenes and EB exhibit many similar properties (see Table 1).

Chemical reactions that the xylenes participate in include (*1*) migration of the methyl groups, (*2*) reaction of the methyl groups, (*3*) reaction of the aromatic ring, and (*4*) complex formation.

Migration of the Methyl Groups. Reactions that involve migration of the methyl groups include isomerization, disproportionation, and dealkylation. The interconversion of the three xylene isomers via isomerization is catalyzed by acids.

Reactions of the Aromatic Ring. The reactions of the aromatic ring of the C_8 aromatic isomers are generally electrophilic substitution reactions. All of the classical electrophilic substitution reactions are possible, but in most instances they are of little practical significance. See also **Friedel-Crafts Reaction**.

Complex Formation. All four C_8 aromatic isomers have a strong tendency to form several different types of complexes. Complexes with electrophilic agents are utilized in xylene separation.

Manufacture of Xylenes

The initial manufacture of mixed xylenes and the subsequent production of high purity PX and OX consists of a series of stages in which (*1*) the mixed xylenes are initially produced; (*2*) PX and/or OX are separated from the mixed xylenes stream; and (*3*) the PX- (and perhaps OX-) depleted xylene stream is isomerized back to an equilibrium mixture of xylenes and then recycled back to the separation step. These steps are discussed below.

Mixed Xylenes Production Via Reforming. Two principal methods for producing xylenes are catalytic reforming and toluene disproportionation. In reforming, a light fraction from a straight run petroleum fraction or from an isocracker is fed to a catalytic reformer. This is followed by heart-cutting and extraction. The mixed xylenes stream must then be processed further to produce high purity PX and/or OX. However, because of the close

[c] To convert J to cal, divide by 4.184.

boiling points of PX and MX, using distillation to produce high purity PX is impractical. Instead, other separation methods such as crystallization and adsorption are used.

Xylenes Production Via Toluene Transalkylation and Disproportionation. The toluene that is produced from processes such as catalytic reforming can be converted into xylenes via transalkylation and disproportionation. Toluene disproportionation is defined as the reaction of 2 mol of toluene to produce 1 mol of xylene and 1 mol of benzene. Toluene transalkylation is defined as the reaction of toluene with C_9 or higher aromatics to produce xylenes.

Separation Processes for PX. There are essentially two methods that are currently used commercially to separate and produce high purity PX: (*1*) crystallization and (*2*) adsorption. A third method, a hybrid crystallization/adsorption process, has been successfully field-demonstrated.

Low temperature fractional crystallization was the first and for many years the only commercial technique for separating PX from mixed xylenes. PX has a much higher freezing point than the other xylene isomers. Thus, upon cooling, a pure solid phase of PX crystallizes first. Eventually, upon further cooling, a temperature is reached where solid crystals of another isomer also form. This is called the eutectic point. The solid PX crystals are typically separated from the mother liquor by filtration or centrifugation.

Adsorption represents the second and newer method for separating and producing high purity PX. In this process, adsorbents such as molecular sieves are used to produce high purity PX by preferentially removing PX from mixed xylene streams. Separation is accomplished by exploiting the differences in affinity of the adsorbent for PX, relative to the other C_8 isomers. The adsorbed PX is subsequently removed from the adsorbent by displacement with a desorbent.

In 1994, IFP and Chevron announced the development of a hybrid process that reportedly combines the best features of adsorption and crystallization. In this process, the adsorbent bed is used to initially produce PX of 90–95% purity. The PX product from the adsorption section is then further purified in a small single-stage crystallizer and the filtrate is recycled back to the adsorption section. It is reported that ultra-high (99.9 + %) purity PX can be produced easily and economically with this scheme.

MX Separation Process. The Mitsubishi Gas–Chemical Company (MGCC) has commercialized a process for separating and producing high purity MX. This process is based on the formation of a complex between MX and $HF–BF_3$. MX is the most basic xylene, and its complex with $HF–BF_3$ is the most stable.

MX of >99% purity can be obtained with the MGCC process with <1% MX left in the raffinate by phase separation of hydrocarbon layer from the complex-HF layer. The latter undergoes thermal decomposition, which liberates the components of the complex.

Xylene Isomerization. After separation of the preferred xylenes, i.e., PX or OX, using the adsorption or crystallization processes discussed herein, the remaining raffinate stream, which tends to be rich in MX, is typically fed to a xylenes isomerization unit in order to further produce the preferred xylenes. Isomerization units are fixed-bed catalytic processes that are used to produce a close-to-equilibrium mixture of the xylenes. The catalysts are also designed to convert EB to either xylenes, benzene and lights, or benzene and diethylbenzene.

Health and Safety Factors

The xylene isomers are flammable liquids and should be stored in approved closed containers with appropriate labels and away from heat and open flames. The vapor can travel along the ground to an ignition source. In the event of fire, foam, carbon dioxide, and dry chemical are preferred extinguishers. The xylenes are mildly toxic. They are mild skin irritants, and skin protection and the cannister-type masks are recommended.

Uses

The majority of xylenes, which are mostly produced by catalytic reforming or petroleum fractions, are used in motor gasoline. The majority of the xylenes that are recovered for petrochemicals use are used to produce PX and OX. PX is the most important commercial isomer.

Almost all of the OX that is recovered is used to produce phthalic anhydride, the phthalic anhydride is a basic building block for plasticizers used in flexible PVC resins, for polyester resins used in glass-reinforced plastics, and for alkyd resins used for surface coatings. Some of the mixed xylenes that are produced are used as solvents in the paints and coatings industry. However, this use has declined.

Y

YAG AND YIG. Synthetic yttrium aluminum and yttrium iron garnets, respectively. These materials were developed in the mid-1960s. They are pressed and sintered polycrystalline ceramics and are made by a solid-state reaction of Y_2O_3 with iron oxide or aluminum oxide. Garnets operate in microwave bandpass (filters) circulators and isolators in telephone, radar, and space-communication networks. The original electronic use led to the development of single-crystal yttrium aluminum garnets which approach the brilliance and hardness of diamond. Yttrium oxide is the base for neodymium-doped laser crystals. See also **Neodymium**; **Rare-Earth Elements and Metals**; and **Yttrium**.

YEASTS AND MOLDS. These are very important plant organisms that make both positive and negative contributions to mammalian life processes. Their plus and minus values are particularly noted in connection with the production and storage of food products.

Taxonomy

Plants that lack true roots, stems, or leaves, and that are without highly-organized conducting systems are called *simple plants*, and they make up the phylum *Thallophyta*. The two subdivisions of *Thallophyta* are *algae* and *fungi*. Algae have chlorophyll; fungi do not. Fungi utilize carbohydrates that are synthesized by green plants. Fungi are classified as *parasites* or *saprophytes*, the latter obtaining food from nonliving organic material. The science of fungi is *mycology*. See also **Fungus**.

The fungi include: *Slime molds* (*Myxomycetes*); *algal fungi* (*Phycomycetes*); *sac fungi* (*Ascomycetes*); and *club fungi* (*Basidiomycetes*); among others. The yeasts and most of the molds with which food products are associated in some way are of the *Ascomycetes* variety.

The varied interface between the *Ascomycetes* and foods ranges from their very negative, parasitic habit on certain crops (exemplified by Chestnut blight fungus; or ergot on grains) and their causative involvement in certain foodborne diseases to their positive use in connection with the production (notably by fermentation) of major food products, such as bread and wine.

The term *yeast* is used to describe a relatively small number of *Ascomycetes* fungi (a few hundred— Lodder et al. (1970) classified 349 fermentative species, of which relatively few are used industrially), as compared with the vast number of other fungi (several thousand) that have been identified.

The term *mold* does not have a clear cut mycological definition. While the yeasts have a preponderantly positive value in food production and utilization, the molds make some positive contributions (some cheeses, etc.), but they participate in many more negative ways (leaf molds on plants; blue-green molds on fruits; machinery mold; causes of some foodborne diseases; etc.). Some authorities identify all or most mold as *saprophytes*, as previously defined. This identification, however, is not fully satisfactory in terms of the present loose ways in which the word mold is used in the professional literature. Molds do play an important role in the *biodegradation* of unwanted substances.

Yeasts

The importance of the economically useful yeasts can be attributed to two main factors: (1) *fermentation*—the transformation of simple sugars and other organic chemicals to other, more desirable chemicals; and (2) *respiratory* (*oxidative*) *metabolism*—the great capacity of some yeasts for a protein synthesis during growth in richly aerated media containing a wide variety of carbonaceous and nitrogenous nutrients. Thus, yeasts serve in many ways: (1) As living cells, they are biocatalysts in the production of bread, wine, beer, distilled beverages, among other important food products. (2) As dried, nonfermentative whole cells or hydrolyzed cell matter, yeasts contribute nutrition and flavor to human diets and animal rations. (3) As producers of vitamins and other biochemicals, yeasts are a rich source of enzymes, coenzymes, nucleic acids, nucleotides, sterols, and metabolic intermediates. See also **Coenzymes**; **Enzyme**; and **Enzyme Preparations**. (4) As a versatile biochemical tool, yeasts aid research studies in nutrition, enzymology, and molecular biology.

Background

It is estimated that the arts of making wine, leavened bread, and beer were practiced more than 4000 years ago. The phenomena for producing these foods were attributed to "yeast" at an early age. In many languages, the word for yeast describes the visible effects of fermentation, as observed in the expansion of bread dough and the accumulation of froth or barm on the surface of fermenting juices and mashes. Historically, it has been reported that yeast cells were first seen in a droplet of beer mounted on a slide in a crude microscope used by van Leeuwenhoek in 1680. He found globular bodies, but was not aware that they were living forms. For nearly two centuries the theory of spontaneous generation dominated thought and research on the causes of fermentation and disease. In 1818, Erxleben described beer yeast as a living vegetable matter responsible for fermentation. In the following twenty years, yeasts were shown to reproduce by budding and, in 1837, Meyen named yeast *Saccharomyces*, or "sugar fungus." By 1839, Schwann observed "endospores" in yeast cells, later named ascospores by Reess. As early as 1857, Pasteur proved the biological nature of fermentation and later, in 1876, Pasteur demonstrated that yeast can shift its metabolism from a fermentative to an oxidative pathway when subjected to aeration. This shift, then named the Pasteur effect, is especially characteristic of bakers' yeast (*Saccharomyces cerevisiae*) and is applied in the large-scale production of yeasts.

Botanically, yeasts form a heterogeneous group of saprophytic forms of life occurring naturally on the surface of fruits, in honey, exudates of trees, and in soil. They are disseminated by airborne dusts, insects, and animals. Typically, industrial yeasts are generally oval, microscopic, unicellular organisms. In addition to lacking chlorophyll, they also lack locomotion. They reproduce vegetatively by budding and sexually by spore formation (ascospores) within the mother cell or ascus. These properties place them in the family *Endomycetacea* of the class *Ascomycetes*, as previously mentioned. Among the most important industrial yeasts are:

Saccharomyces cerevisiae (alcoholic beverages and bread)
S. cerevisiae var. *ellipsoideus; S. bayanus*; and *S. beticus* (wines)
S. uvarium (formerly called *S. carlsbergensis*) (beer, ale, etc.)
Kluyveromyces fragilis (formerly called *S. fragilis*) (whey disposal)

Food and feed yeast production employ several molds in the family *Cryptococcaceae: Candida utilis, C. tropicalis*, and *C. japonica*, which are cultivated on plant wastes (wood sugars, molasses, stillage), and C. lipolytica, which converts hydrocarbons to yeast protein.

Properties of Yeasts

The cell structure of *S. cerevisiae*, as observed in the optical microscope, reveals a rigid cell wall, a colorless, granular cytoplasm, and one or more vacuoles. Dimensions of a typical bakers' yeast are about 4 to 6 by 7 to 10 micrometers. Electron microscopy of ultrathin sections of a yeast cell show the microstructures, including: birth and bud scars on the cell wall, plasmalemma (cytoplasmic membrane), nucleus, mitochondria, vacuoles, fat globules, cytoplasmic matrix and volution or polyphosphate bodies. The cell walls of bakers' yeast contain 30–35% glucan (yeast cellulose), 30% mannan (yeast gum), which is bound to protein (about 7%), 1–2% chitin, 8–13% lipid material, plus inorganic components, largely phosphates.

Gross chemical composition of compressed bakers' yeast is approximately 70% moisture. The dry matter is made up of 55% protein (N × 6.25), 6% ash, 1.5% fat, and the remainder mostly polysaccharides, including about 15% glycogen and 8% trehalose.

Food yeast, molasses-grown, is dried to about 5% moisture and has the same chemical composition as bakers' yeast. In terms of micrograms per gram of yeast, the vitamin content is: 165 thiamine; 100 riboflavin; 590 niacin; 20 pyridoxine; 13 folacin; 100 pantothenic acid; 0.6 biotin; 160 para-aminobenzoic acid; 2710 choline; and 3000 inositol. Yeast crude protein contains 80% amino acids; 12% nucleic acids; and 8% ammonia. The latter components lower the true protein content to 40% of the dry cell weight.

Yeast protein is easily digested (87%) and provides amino acids essential to human nutrition. Most commercial yeasts show the following pattern of amino acids, among others, as percent of protein: 8.2% lysine; 5.5% valine; 7.9% leucine; 2.5% methionine; 4.5% phenylalanine; 1.2% tryptophan; 1.6% cystine; 4% histidine; 5% tyrosine; and 5% arginine. The usual therapeutic dose of dried yeast is 40 grams/day, which supplies significant daily needs of thiamine, riboflavin, niacin, pyridoxine, and general protein.

The ash content of food yeasts ranges from 6 to 8% (dry basis), consisting mainly of calcium, phosphorus, and potassium. Contained in quantities of less than 1% are magnesium, sulfur, and sodium. At the microgram level are included iron, copper, lead, manganese, and iodine.

Triglycerides, lecithin, and ergosterol are the main constituents of yeast lipid (fat). Oleic and palmitic acids predominate in yeast fat. These resemble the composition of common vegetable fats. Ergosterol, the precursor of calciferol (vitamin D_2) varies from 1 to 3% of yeast dry matter.

Metabolic Activity

This is generally associated with the familiar alcoholic fermentation in which theoretically 100 parts of glucose are converted to 51.1 parts of ethyl alcohol (ethanol), 48.9 parts of carbon dioxide (CO_2), and heat. In addition, however, the anaerobic reaction also yields minor byproducts in small amounts—mainly glycerol, succinic acid, higher alcohols (fusel oil), 2,3-butanediol, and traces of acetaldehyde, acetic acid, and lactic acid. Fusel oil is a mixture of alcohols, including *n*-propyl, *n*-butyl, isobutyl, amyl, and isoamyl alcohols.

Respiratory activity of oxidative dissimilation is characteristic of many species of yeasts. During aerobic growth, sugar is oxidized to carbon dioxide and water, with release of large amounts of energy (about 680 kcal when complete oxidation occurs). Aerobiosis produces a variety of byproducts, some in unusually high concentration, such as acetic acid, succinic acid, zymonic acid, polyhydric alcohols (glycerol, erythritol, etc), extracellular lipids, carotenoid pigments in shades of red and yellow, black pigment (melanin), and capsular polysaccharides (phosphomannan).

Production

Well over 85,000 tons (76,500 metric tons) of yeast dry matter are produced in the United States alone each year. About 75% of this is in the form of bakers' yeast, the remaining 25% represents about equal amounts of food yeast and feed yeast. This production issues from four types of manufacture: (1) Bakers' yeast is grown batchwise in aerated molasses solutions. (2) *Candida utilis* is obtained from wood pulp mill spent liquid. (3) *K. fragilis* is grown batchwise in cottage cheese whey. (4) Dried yeast is recovered as spent beer yeast. Worldwide production of all types of food and feed yeast is estimated at more than 450,000 dry tons (405,000 metric tons) per year.

The process for growing bakers' yeast is a model system for the propagation of microorganisms. The process commences with a laboratory culture of a pure strain of *S. cerevisiae*. Seed yeast is developed in successively larger volumes of nutrient solutions, beginning with a Pasteur flask and ending in a fermenting tank containing as much as 40,000 gallons (1514 hectoliters) of sterilized and diluted molasses maintained at 30°C. During the highly aerated growth period, minerals are added, pH is adjusted to 4.5, and diluted molasses is continuously fed in proportion to the increase in cell mass. Under ideal conditions, yeast cells may double in number every 2.5 hours, converting more than half (56.7%) of the sugar supplied to cell components. Biosynthesis of cell matter requires an equal amount of oxygen. To produce 100 weight units of yeast dry matter with 50% protein content requires about 400 weight units of molasses, 25 weight units of aqua ammonia, 15 weight units of ammonium sulfate, and 7 weight units of monobasic ammonium phosphate. For each 100 pounds of dry yeast, 75,000 cubic feet of air are required; for 100 kilograms of dry yeast, 4,683 cubic meters of air are needed.

Fermentation Processes

The biochemistry of alcoholic fermentation involves a series of internal enzyme-mediated oxidation-reduction reactions in which glucose is degraded via the Embden-Meyerhof-Parnas pathway. See also **Carbohydrates**; and **Glycolysis**.

Some typical reactions performed by yeasts are listed in the Table 1.

Post-Processing Spoilage of Food by Yeasts

Microbiological spoilage of food is a competitive process occurring among yeasts, bacteria, and molds. Yeasts normally play a small role in spoilage, because they constitute only a small portion of the initial population, because they grow slowly in comparison with most bacteria, and because their growth may be limited by metabolic substances produced by bacteria. Evidence does not show food poisoning as caused by the presence of spoilage yeasts in foods. The byproducts of metabolism are not considered toxic and, while there are a few yeasts that may be considered pathogenic, they are not known to be responsible for foodborne infections or intoxications (Walker, 1977; Peppler, 1977). The metabolism of yeasts can result in the development of unnatural flavors and odors and changes in pH because of the utilization of organic acids important in fermented foods. Many yeasts are capable of utilizing lactic, acetic, and citric acids, which are essential for production of flavor and for preservation of some foods. Decreased concentration of these acids causes an increased pH and produces conditions that favor growth of spoilage bacteria. Normally, several factors interact to establish conditions that favor growth and subsequent spoilage of foods by yeasts. Examples of food spoilage by yeasts are given in the lower half of Table 1.

Although yeasts are abundant in nature, notably on leaves and in the soil, they do not compete with bacteria and molds as sources of major problems. But, in assessing the potential for spoilage by yeasts, one must consider those factors which are favorable or unfavorable to the growth and multiplication of yeast populations. Availability of oxygen is important. No yeast is known that can grow under strictly anaerobic conditions; thus, all require oxygen to be present in some proportion. Temperature is also an important factor. Yeasts are not heat resistant in the sense that bacterial endospores are heat resistant. Most yeasts cannot withstand temperatures above 65–70°C. The majority of yeast species have an optimum temperature for growth between 20 and 30°C. Even though yeasts are very resistant to low temperatures and can survive frozen storage, they normally are not a major problem in spoilage of frozen or refrigerated foods. In refrigerated foods, psychrotrophic bacteria rapidly outnumber the yeasts, the latter constituting a minor part of the initial population. However, where antibiotics or ionizing radiation have been used to reduce or inhibit bacterial growth, then yeast population may predominate. If the definition of a *psychrophilic* organism is one that has an optimum temperature below 20°C, then there are a number of strains of psychrophilic yeasts.

The survival and growth of all organisms is dependent on the presence of some water in the environment. Yeasts generally require more moisture for growth than molds, but less than bacteria. Systems containing high concentrations of sugar or salt have low a_w values or high osmotic pressure (Walker, 1977). Organisms growing in such systems are usually referred to as being *osmophilic*. A number of investigators have not been able to find any yeast that is clearly osmophilic. Windisch (1969) suggested the term osmotolerant to describe some yeasts. It is important to note that yeasts that normally will not grow in a high-sugar environment may appear, if the substance has been exposed to the air sufficiently to absorb water and dilute spots or edges of the material, thus favoring yeast growth. Species such as *Saccharomyces rouxii, S. rouxii* var. *polymorphus*, and *S. mellis* (Lodder, 1952) are capable of spoiling high-sugar foods, such as honey, maple sugar, sugar cane syrups, molasses, fruit syrups, candy, crystallized fruits, jams, jellies, and dried fruits. It is not uncommon for dried figs and prunes to be covered with a white coating of yeast during storage. The foods have a typical fermented odor and may contain gas pockets. This coating normally is a mixture of sugar and yeasts, with the principal yeast being *Schizosaccharomyces octosporus*.

Molds

The most critical factor in mold growth is the availability of sufficient moisture. Molds are widely distributed throughout nature. Chemicals for

TABLE 1. REACTIONS IN WHICH YEASTS PARTICIPATE[1]

Type of reaction	Number of known reactions	Examples of reactions
Reduction	156	Diacetyl to acetoin (in beer); cinnamic aldehyde to cinnamic alcohol.
Decarboxylation	21	Malic acid to lactic acid (in wines); amino acids to amines (histamine and tyramine accumulate in soft cheeses because of surface growth of *Torulopsis candida* and *Debaryomyces kloeckera*).
Deamination	17	Examples of deamination and decarboxylation include conversion of amino acids to fusel oil (leucine to isoamyl alcohol, isoleucine to amyl alcohol, and phenylalanine to phenyl ethanol). Fusel oil formation is a normal function of all yeast fermentations (in alcoholic beverages, levels range from trace to 2200 parts per million). Deamination: Glutamic acid to gamma-OH-butyric acid (*S. cerevisiae*).
Oxidation	14	Acids, alcohols, sugars, hydrocarbons. Also stepwise: alcohol to aldehyde or acid (sake yeast).
Esterification	10	Ethyl acetate (*Hansenula anomala*).
Condensation	9	Acetaldehyde to acetoin; acetaldehyde to pyruvic acid to alpha-acetolactic acid.
Hydrolysis	5	Starch hydrolysis: By *Endomycopsis fibuligera*; artichoke starch (insulin) by *Kluyveromyces fragilis*.
Amination	1	

Examples of Lesser-known Properties and Characteristics of Yeasts

Type of reaction	Yeasts involved	Examples
Lipolysis	*Candida lipolytica; C. rugosa; Torulopsis sphaerica*	Mainly in butter, margarine, and cheese.
Proteolysis	*C. lipolytica; T. sphaerica*	Especially on soft cheese surfaces.
Pectinolysis	*Saccharomyces kluyveri; Kluyveromyces fragilis; Hansenula anomala*	Softening of olives and cherries in brines, followed by formation of gas pockets in fruit. Strains of wine yeasts contain polygalacturonases which, during fermentation of grape juice, participate in the solubilization of pectin.
Acid formation	Species of Brettanomyces, Hansenula, Pichia, Saccharomyces	As a contaminant in wines, Brettanomyces spp. Forms a higher concentration of volatile acids (also isobutyric and isovaleric acids) than *S. cerevisiae*. Pichia species and other yeasts are responsible for acetic acid production in brines of domestic green olives; not lactobacilli, as assumed for years (Vaughn et al., 1976).
Pigmentation	*Rhodotorula glutinis*. Sporobolomyces spp.	Carotenoids (pink, red); *Rhodotorula glutinis causes* pink sauerkraut and discolors the surface of high-moisture cheeses.
Esterification	Species of Hansenula, Kluyveromyces, Brettanomyces	Ethyl acetate and ethyl lactate in cottage cheese and shredded Mozzarella cheese. See also **Milk and Milk Products**.
Turbidity formation	In wine: *Saccharomyces bailii, S. chevalieri*, Brettanomyces spp. In beer: *S. diastaticus, S. bayanus*	In soft drinks; in wine: *S. bailli, S. chevalieri*; in beer: *S. diastaticus, S. bayannus*.

[1] Based, in part, upon Peppler et al. (1977).

the destruction of molds, including those in the soil, are mentioned in the entry on **Antimicrobial Agents (Foods)**. In addition to food spoilage, various molds can be destructive of various materials, notably of substances prepared from animal skins, such as leather, book covers, shoes, and materials prepared from vegetable substances, such as paper and wood products. In warm, humid areas, mold (mildew) grows on wooden structures, including painted surfaces unless these have been chemically treated. In the case of foods, molds cause innumerable problems during the full cycle of food production.

Storage temperature of food is less important than the presence of moisture, since fungi can grow and produce toxins over a wider span of temperatures than can any other microorganisms. Most species are able to grow at an a_w of 0.8 to 0.88; while xerophilic types can grow at an a_w of 0.65 to 0.75. A relative humidity of from 70 to 90% establishes suitable moisture equilibrium for initiation of mold growth and toxin formation in numerous food products. See also **Activity Coefficient**.

Unfortunately for the would-be consumer of food, fungal contamination is not always immediately apparent and thus may not seem to be cause either for the rejection of food by humans or for the rejection of feedstuffs by livestock. Concentrations of mold organisms are not always easy to see or to smell. Further, the relative stability of most mycotoxins to heat precludes the use of cooking as a detoxifying procedure. Among the most aggressive of the molds are species of *Candida, Aspergillus, Rhizopus*, and *Mucor*. Several of the fungi are not pathogenic to healthy humans, but may be virulent pathogens in debilitated persons, or those treated with broad-spectrum antibacterial drugs, or immunosuppressive measures. An example of this type of organism is *Cryptococcus neoformans* (Davis, 1973). Many of the fungi produce disease through infection rather than through mycotoxin production, but this usually requires predisposing factors.

Milner and Geddes pointed out in 1946 that the aflatoxigenic organism *Aspergillus flavus* is a common soil fungus throughout the world, and aflatoxin-contaminated food has been noted in many countries for a number of years (Wogan, 1966). Crops, such as groundnuts (peanuts), in intimate contact with soils, are likely to contact the necessary mold inoculum for aflatoxin production, resulting in toxin formation upon storage in air.

Several investigators have shown that toxic strains of *Fusarium, Cladosporium, Penicillium*, and *Mucor* can sporulate and grow at temperatures well below 0°C. It also has been shown that toxin formation can be associated with overwintering of grain in the field. In some varieties of barley, such as Siri and Mala, the incidence of *Aspergillus* and

Penicillium species is related solely to temperature and moisture storage conditions and is not correlated to the percentage of unripe grains. Low humidities tend to predispose hosts to invasion by molds by causing them to lose turgor. Mold is the cause of serious problems in connection with rice. The predominant molds present in wild rice during fermentation curing are *Mucor*, aflatoxigenic and nontoxigenic *Aspergillus, Penicillium*, and *Rhizopus* species. Most of the B_1 aflatoxin is in the hulls and the level of the toxin can be reduced by parching, which serves to reduce, but not fully destroy molds.

Contamination of soybeans with *Aspergillus flavus* is found in approximately 50% of commercial samples. Fortunately, the incidence of aflatoxin from this route is quite low. Moisture at the time of maturity, development of the seed in a closed pod, and binding of zinc by phytic acid are suggested as reasons for resistance of soybeans to aflatoxin production.

The most active sugar contaminants are molds, particularly *Aspergillus*. Penicillium growth on cheddar cheese results in a pH gradient, increasing to a pH of 8 at the surface. Mycotoxins diffuse through foods and are not removed when the surface molds are removed. Therefore, molds of unknown variety or origin should not be ingested. On the other hand, many of the common molds found as contaminants of Western foods are used in Asian fermented foods and beverages, principally as sources of flavor.

Degradation of Aflatoxin

Numerous researchers have investigated a variety of chemical and physical means for degrading aflatoxin. These include the use of irradiation, heat, acids and bases, oxidizing agents, bisulfite, and biological agents. The practical application of ultraviolet radiation to date has not proved successful. Aflatoxin is quite heat stable. Numerous investigators have concluded that although heat can degrade aflatoxins, it is not an effective and economically feasible means for inactivating these toxins when present in foods or feeds.

Among oxidizers used have been sodium hypochlorite, potassium permanganate, and hydrogen peroxide. Bisulfite is commonly used in the wet milling of corn (maize) and in processing wines, fruit juices, jams, and dried fruits.

Machinery Mold

This mold generally refers to the buildup of the organism *Geotrichum candidum* on food-contact factory equipment in processing plants. The term *dairy mold* is used in the processing of milk to identify this mold.

Since passage of the original Federal Food and Drugs Act of 1906 (United States), the presence of machinery mold in any food processing plant is a violation of regulations. Antimicrobial agents have made it possible to keep machinery clear of this mold. The mold can be particularly bothersome in tomato and pineapple processing plants. See also **Antimicrobial Agents (Foods)**.

YEAST INHIBITORS. See **Antimicrobial Agents (Foods)**.

YTTERBIUM. [CAS: 7440-64-4]. Chemical element symbol Yb, at. no. 70, at. wt. 173.04, thirteenth in the Lanthanide Series in the periodic table, mp 819°C, bp 1196°C, density 6.966 g/cm^3 (20°C). Elemental ytterbium has a face-centered cubic crystal structure at 25°C. The pure metallic ytterbium is silver-gray in color and is stable in moist or dry air up to 200°C, after which oxidation occurs. The metal is readily dissolved by dilute and concentrated mineral acids. The metal dissolves in liquid NH_3 to yield a dark-blue color. There are seven natural isotopes ^{168}Yb, ^{170}Yb through ^{174}Yb, and ^{176}Yb. Ten artificially-produced isotopes have been identified. Ytterbium is one of the least abundant elements of the rare-earth group and 53rd among all elements occurring in the earth's crust. The element was first identified by J.D.G. Marignac in 1878. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{13} 5s^2 5p^6 5d^1 6s^2.$$

Ionic radius Yb^{2+} 1.00 Å; Yb^{+3} 0.88 Å. Metallic radius 1.940Å. First ionization potential 6.25 eV; second 12.18 eV. Other important physical properties of ytterbium are given under **Rare-Earth Elements and Metals**.

The principal sources of ytterbium are euxenite, gadolinite, monazite, and xenotime, the latter being the most important. Ytterbium is separated from a mixture of yttrium and the heavy Lanthanides by using the sodium amalgam reduction technique. Ytterbium metal is obtained by heating a mixture of lanthanum metal and ytterbium oxide under high vacuum. The ytterbium sublimes and is collected on condenser plates whereas the lanthanum is oxidized to the sesquioxide.

To date, the major uses of ytterbium have been in applied and fundamental research. The element and its compounds have been used in magnetic "bubble" domain devices (ytterbium orthoferrite), in phosphors to convert infrared to visible light, in lasers, and radioisotope ^{169}Yb has found application in portable industrial and medical radiographic units.

YTTRIUM. [CAS: 7440-65-5]. Chemical element symbol Y, at. no. 39, at. wt. 88.905, periodic table group 3, mp 1522°C, bp 3,338°C, density 4.469 g/cm^3 (20°C). Most of the properties of yttrium are similar to those of the heavy rare-earth elements, falling between gadolinium and erbium. Elemental yttrium has a close-packed hexagonal crystal structure at 25°C. The pure metallic yttrium is silver-gray in color, retaining a luster in air up to about 400°C, above which it oxidizes to Y_2O_3. The metal is dissolved by most mineral acids, but is relatively inert in a 1:1 mixture of concentrated HNO_3 and 48% hydrofluoric acid. Yttrium is capable of working common metallurgical fabrication procedures. The metal is immiscible with liquid or solid uranium metal. It has a low thermal-neutron-absorption cross section and a low acute-toxicity rating. The natural isotope of yttrium is ^{89}Y. Fourteen artificial isotopes have been identified. See also **Radioactivity**. In terms of abundance, yttrium is present on the average of 33 ppm in the earth's crust and potentially is as plentiful as cobalt. The element was first identified by Fredrich Wohler in 1828. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^1 5s^2$. Ionic radius Y^3+ 0.900 Å. Metallic radius 1.801 Å. First ionization potential 6.38 eV;

second 12.24 eV. Other important physical properties of yttrium are given under **Chemical Elements**; and **Rare-Earth Elements and Metals**.

Residues from uranium mining operations in Canada have been a major source of yttrium. Xenotime (YPO_4) found in Malaysia is another source, as well as the ion-adsorption clay minerals in China. Some apatite deposits are unusually rich in yttrium and it also is found in gadolinite, euxenite, and samarskite.

In recovering yttrium, mixed rare-earth minerals or wastes are dissolved in HNO_3 or H_2SO_4. Liquid-liquid organic ion-exchange solvent extraction cells then separate a pure yttrium fraction, usually precipitated as an oxalate and then calcined to the oxide. The metal is obtained by metallothermic reduction, using calcium mixed with YCl_3 or YF_3 in a sealed retort at a temperature in excess of 1,550°C. Alloys of yttrium and cobalt, or yttrium and magnesium have been deposited out of a molten electrolyte BaF_2-LiF-YF_3.

The major uses of yttrium are as phosphors in color television, computer monitors, trichromatic fluorescent lights, x-ray intensifying screens and temperature sensors. Yttrium oxide stabilized zirconium oxide is used as oxygen sensors for automobile engines and in iron making, wear-resistant and corrosion-resistant cutting tools, abrasives, high temperature refractories for continuous casing nozzles, jet engine coatings, simulated diamond gemstones (i.e. cubic zirconia), and as a solid electrolyte in solid oxide fuel cells (SOFC). Yttrium aluminum garnets are used as laser crystals for industrial cutting and welding, medical and dental surgery, temperature and distance sensing, photochemistry, photoluminescence, digital communication and non-linear optics. $YBa_2Cu_3O_{7-x}$ is an important high temperature ceramic superconductor with a 90 K superconducting transition temperature. It is primarily used in the form of thin films for superconducting electronics (such as SQUIDS, MRI and NMR coils, wireless communication subsystems and digital instruments) and as superconducting wires and tapes for power transmission lines, motors and generators, transformers, current limiters, magnetic separation, research magnet systems and current leads. Yttrium-iron garnets find use as microwave bandpass filters, circulators, and isolators in electronic and communications circuitry. Y_2O_3 is used as a metallurgical dispersion hardening agent in nickel-based superalloys made by powder metallurgy techniques. Yttrium metal also is specified in several cobalt-base superalloys in which it improves hot corrosion (sulfidation) resistance at high temperatures. When used in iron-chromium-aluminum alloys, yttrium improves workability and adds resistance to sag when the alloys are used as electrical-heating elements. The metal also is applied as cladding to rotating turbine engine parts to obtain superior oxidation resistance. Yttrium also has been used in permanent magnets, YCo_5, and shows great promise. These magnets are second only to $PrCo_5$ as the most powerful permanent magnet materials developed to date, far exceeding alnico and other more conventional materials.

Chemistry and Compounds

Yttrium hydroxide, $Y(OH)_3$ is precipitated by NH_4OH from solutions of yttrium salts. It differs in properties from the lanthanide hydroxides, both structurally and chemically, in its ability to absorb atmospheric CO_2. Yttrium oxide, Y_2O_3, is obtained by heating the hydroxide or oxy-acid salts; it forms mixed oxides when heated with other oxides, such as Fe_2O_3 and TiO_2. Yttrium also forms a peroxide, Y_4O_9, obtained in hydrated form by treatment of yttrium solutions with hydrogen peroxide.

All four halides are known. The fluoride, YF_3, is readily formed by action of a fluoride on an yttrium nitrate solution. There is an oxyfluoride, YOF, formed by high-temperature, low-pressure heating of the mixed oxide and fluoride. Complex fluorides, containing $[YF_6]^{3-}$ exist; the cryolite minerals are of this composition. The group, $-YF_4$ is found in double salts formed by YF_3 and the alkali fluorides. The chloride, YCl_3, is formed as a hydrate by action of HCl solution upon the hydroxide. It may be dehydrated by slow heating; rapid heating gives the oxychloride, YOCl. The bromide, YBr_3, is formed as a hydrate by action of HBr upon the hydroxide. Its dehydration requires heating under vacuum. The iodide, YI_3 is best prepared from the anhydrous chloride, by reacting with Hl and I_2.

Both normal and mixed carbonates are known. The former is precipitated, as $Y_2(CO_3)_3 \cdot 3H_2O$ from Y^{3+} solutions by alkali metal carbonates, which in excess dissolve the precipitate to form a soluble hydrated double carbonate. The oxycarbonate is also a double molecule, $3Y_2(CO_3)_3 \cdot 2Y(OH)_3$, formed by action of CO_2, upon the hydroxide.

The nitrate, $(Y(NO)_3)_3)$ exists as a number of hydrates. The hexahydrate formed by action of HNO_3 upon the hydroxide, is dehydrated at 100°C to give the trihydrate and the anhydrous salt. However, other hydrates are known, as well as double nitrates (especially with the lanthanide elements) and oxynitrates, of the general formula, $xY_2O_3 \cdot yN_2O_5 \cdot zH_2O$.

Yttrium hydroxide forms a hydrated sulfate with H_2SO_4, which is dehydrated on heating. It forms double sulfates with alkali and ammonium sulfates.

The carbide, formed from the oxide and carbon in the electric furnace, appears to have the composition, YC_2. It yields acetylene and other hydrocarbons upon hydrolysis.

ZEEMAN EFFECT. An effect of a moderately intense magnetic field upon the structure of the spectrum lines of a gas when subjected to its influence. The phenomenon, sought unsuccessfully by Faraday and finally observed by Zeeman in 1896, consists in the splitting up of each line into two or more components. In the simpler cases, when the source is viewed at right angles to the field, there are three components, of which the middle one has the same frequency as the unmodified line. This component is plane-polarized to vibrate parallel with the field, while the two side components vibrate at right angles to the field. When the source is viewed in the direction of the field, there are only two components, displaced in opposite directions, and circularly polarized in opposite senses. These phenomena constitute the so-called "normal" Zeeman effect. See also **Polarized Light**.

With most lines, however, an anomalous Zeeman effect is observed and the number of components is greater, in some cases reaching twelve or fifteen. They are symmetrically arranged and symmetrically polarized. The displacements, as in the simpler case, are proportional to the magnetic field intensity H, and are always expressible, in wave numbers, as rational multiples of the displacement in the normal effect, which is $4.67 \times 10^{-5} H$ (reciprocal centimeter), a quantity known as the "Lorentz unit." The Zeeman effects observed in sun spots give valuable information as to the magnetic conditions in those areas.

Closely related to the Zeeman effect are two others, the Paschen-Back effect, produced by very strong magnetic fields, and the Back-Goudsmit effect, observed with the spectra of elements having a nuclear magnetic moment, such as bismuth. See also **Chemical Elements**; **Electron Theory**; **Paschen-Back Effect**; and **Stark Effect**.

ZEEMAN, ERIK CHRISTOPHER (1925–). Zeeman was an English mathematician. His doctoral work was in pure mathematics and he received his Ph.D. in 1954 for a thesis on knots and all the algebra you need to actually prove the existence of knots. He did research in topology, which is a type of geometry that examines the properties of shapes in many dimensions. His best known work was in catastrophe theory. His work has consequences for a broad range of fields from weather to psychiatry. Zeeman also made contributions in the development of the chaos theory.

Zeeman is not only known for this mathematical contribution but also for being an excellent educator. He spent much of his life teaching mathematics both to adults and children. He built the mathematics department at University of Warwick in England and made it an internationally known research center. He gave many mathematical talks on radio and television to reach a broader audience feeling that many gifted were amongst the educationally deprived population. He was honored by Queen Elizabeth II knighting him in 1991 for his role in advancing mathematics education. See also **Chemical Elements**; **Electron Theory**; and **Zeeman Effect**.

J.M.I

ZEISBERG CONCENTRATOR. A nitric acid concentrator, consisting of a packed tower, into which weak nitric acid vapors are introduced. Some steam is admitted into the bottom, and strong nitric acid vapors are discharged from the top to a condenser.

ZEISEL REACTION. The demethylation of an organic compound by treatment with hydriodic acid, which leaves a hydroxy group in place of the methoxy group, and forms methyl iodide, which may readily be determined quantitatively, as in the study of the amount of methoxy groups present.

ZEOLITE GROUP. To the zeolite group of minerals belong a number of hydrous silicates of aluminum which also ordinarily contain sodium or calcium, but rarely they may carry barium, strontium, magnesium, and potassium. These minerals are not related crystal- lographically as they occur in the isometric, orthorhombic, hex- agonal, and monoclinic systems, but they are all characterized by the presence of water, up to 10 or 20%, which is easily released with the application of heat. They are all rather soft minerals, hardness, 3.5–5.5; of low specific gravity, 2.0–2.5, and they will decompose readily upon treatment with acid, most of them yielding a gelatinous mass.

The easy fusion, together with the rapid expulsion of water, is responsible for the name of this interesting group; it is derived from the Greek words to boil and a stone, hence zeolite, "a boiling stone." The zeolites are secondary minerals, usually found filling fissures and cavities in the more basic igneous rocks as basalt, and gabbro, but occasionally in the more acidic types as granite or in gneisses. The following members of the zeolite group are described under **Analcime**; **Chabazite**; **Harmotome**; **Heulandite**; **Natrolite**; **Phillipsite**; **Scolecite**; and **Stilbite**.

See also **Molecular Sieves**.

ZEOLITE SOFTENING (Boiler Water). See **Water Treatment (Boiler)**.

ZEOLYTIC CATALYST. See **Petroleum**.

ZEREVITINOV DETERMINATION. A method of analysis of organic compounds containing active hydrogen atoms, as in hydroxy, carboxy, or imino groups, by reaction with methyl magnesium halide to yield methane quantitatively: $ROH + CH_3MgX \longrightarrow CH_4 + ROMgX$.

ZERO-ORDER REACTION. A reaction that has a constant rate, as in the case of certain gases reacting on the surface of a solid when it is almost entirely covered. Under such conditions, the reaction rate may be independent of pressure, and thus, the process is kinetically of zero order.

ZERO POINT ENERGY. The kinetic energy remaining in a substance at the absolute zero point of temperature. According to quantum mechanics, a simple harmonic oscillator does not have a stationary state of zero kinetic energy. The ground state has still one half quantum, $h\nu$, of energy, and the motion corresponding thereto. This agrees with the uncertainty principle, which does not permit the oscillator particle to be absolutely at rest exactly at the origin. In solids the zero-point energy is distributed in the normal modes of lattice vibration, and may be an appreciable term in the binding energy of the crystal, especially in hydrogen, helium, rare gases, etc. The motion may be observed in x-ray diffraction, but does not contribute to electronic resistivity.

ZETA POTENTIAL. The potential across the interface of all solids and liquids. Specifically, the potential across the diffuse layer of ions surrounding a charged colloidal particle, which is largely responsible for colloidal stability. Discharge of the zeta potential, accompanied by precipitation of the colloid, occurs by addition of polyvalent ions of sign opposite to that of the colloidal particles. Zeta potentials can be calculated from electrophoretic mobilities, i.e., the rates at which colloidal particles travel between charged electrodes placed in the solution.

ZIEGLER CATALYST. A type of stereospecific catalyst, usually a chemical complex derived from a transition metal halide and a metal hydride or a metal alkyl. The transition metal may be any of those in groups IV to VIII of the periodic table; the hydride or alkyl metals are those of groups I, II, and III. Typical, titanium chloride is added to aluminum alkyl in a hydrocarbon solvent to form a dispersion or precipitate of the catalyst complex. These catalysts usually operate at atmospheric pressure and are

used to convert ethylene to linear polyethylene and also in stereospecific polymerization of propylene to crystalline polypropylene (Ziegler process).

ZIEGLER, KARL (1898–1973). A German chemist who won the Nobel prize for chemistry in 1963 with Giulio Natta for their discoveries in the field of the chemistry and technology of high polymers. A great deal of his work was concerned with the chemistry of carbon compounds and development of plastics. A recipient of the Swinburne medal from the Plastics Institute of London in 1964. After studying at Marburg he was a professor at Heidelberg.

ZIEGLER METHOD. Cyclization of dinitriles at high dilution in dialkyl ether in the presence of ether-soluble metal alkylanilide and hydrolysis of the resultant imino-nitril with formation of macrocyclic ketones in good yields.

ZIEGLER-NATTA POLYMERIZATION. Polymerization of vinyl monomers under mild conditions using aluminum alkyls and $TiCl_4$ (or other transition element halide) catalyst to give a stereoregulated, or tactic, polymer. These polymers, in which the stereochemistry of the chain is not random have very useful physical properties.

ZIMMERMANN REACTION. The reaction that occurs between methylene ketones and aromatic polynitro compounds in the presence of alkali. When applied to 17-oxosteroids, the colored compounds formed can be used for the quantitative determination of 17-oxosteroids.

ZINC. [CAS: 7440-66-6]. Chemical element, symbol Zn, at. no. 30, at. wt. 65.38, periodic table group 12, mp 419.58°C, bp 907°C, density 7.1 g/cm^3. Elemental zinc has a close-packed hexagonal crystal structure. There are five stable isotopes ^{64}Zn, ^{66}Zn through ^{68}Zn, and ^{70}Zn. Six radioactive isotopes have been identified ^{62}Zn, ^{63}Zn, ^{65}Zn, ^{69}Zn, ^{71}Zn, and ^{72}Zn. With exception of ^{65}Zn which has a half-life of 245 days, the half-lives of the other isotopes are measured in minutes and hours.

Zinc is a bluish-white metal, malleable and ductile at 150°C, but at 180°C it changes rapidly so that at 205°C it may be easily powdered; remains lustrous in dry air but is slightly tarnished in moist air or in water; burns upon heating to vaporization with a bluish flame, forming zinc oxide; soluble in acids—slowly when pure but rapidly on contact with copper or platinum; soluble in alkalies. Discovery prehistoric.

Zinc ranks 27th in order of abundance of the chemical elements in the earth's crust, an estimated 0.004% content of igneous rocks on an average basis. It is estimated that a cubic mile of seawater contains about 48 tons of zinc. First ionization potential 9.391 eV; second, 17.89 eV. Oxidation potential $Zn \longrightarrow Zn^{2+} + 2e^-$, 0.762 V; $Zn + 4OH^- \longrightarrow ZnO22^- + 2H_2O + 2e^-$, 1.216 V. Electron configuration $1s^2 2s^2 2p^6 3s^2 3p^{10} 4s^2$. Ionic radius Zn^{+2} 0.75 Å. Metallic radius 1.3324_5 Å. Other physical properties of zinc are described under **Chemical Elements**.

Zinc and lead usually occur together in nature as sulfides. Earlier separation processes involved the fine grinding of the combined sulfides and then treating the particles with chemical reagents to cause one sulfide to be preferentially wetted and thus the two sulfides separated by the froth flotation process. In a first stage, the lead sulfide is floated while the zinc sulfide sinks to the bottom of the tank. In the second stage, the process is reversed and the zinc sulfide is floated. Gangue and other nonmetals collect at the bottom of the tank. The separated sulfides are dewatered to a 6–7% moisture content and are referred to as the zinc concentrate and the lead concentrate.

A major zinc ore is ZnS (sphalerite) which frequently occurs with the major lead ore PbS (galena). The lead-zinc ores usually contain recoverable quantities of copper, silver, antimony, and bismuth as well, Major deposits of this type are worked in Australia, the United States, Canada, Mexico, Peru, the former Yugoslav Republics, and the former Soviet Union. Two other important zinc ores are $ZnCO_3$ (smithsonite) and iron-zinc-manganese oxide (franklinite). Several of these minerals are described under separate alphabetical entries.

Extractive Metallurgy of Zinc[1]

As of the early 1980s, zinc production throughout the world is based almost exclusively on two processes:

1. Electrolytic Process—in which oxidized zinc concentrates are leached in sulfuric acid and then electrolyzed to plate SHG (special high-grade zinc metal) on the cathode and to regenerate the acid on the anode.
2. ISP (Imperial Smelting Process)—a combined lead-zinc process in which oxidized concentrates are reduced with coke in a shaft furnace and the zinc vapor collected in a lead splash condenser.

The older retort and electrothermic processes have largely been replaced because of environmental and economic reasons.

The ISP evolved to fill a very special niche in nonferrous metallurgy because of its capability of treating lead-zinc concentrates which may also contain appreciable amounts of copper. The concentrate is normally oxidized in a sintering machine to produce a feed for the blast furnace where the zinc oxide is reduced with coke. Some effort has been underway to develop a hot briquetting operation to produce a suitable feed without sintering. Other efforts to improve the economic competitiveness of the process include air preheat and the use of an oxygen-enriched blast to reduce coke consumption.

Although the electrolytic zinc process can trace its industrial history back over 60 years, only during the last 15 to 20 years has it become the industry standard, commanding a large portion of the free world's zinc capacity. While the electrolytic zinc process has been varied to meet the demands of the particular feed, the flow sheet always contains the basic steps of roasting, leaching, solution purification, and electrolysis. The zinc concentrate is oxidized with air to produce acid-soluble zinc oxide (calcine), and sulfur dioxide-containing off gas suitable for conversion to acid, as well as byproduct steam. The Vieille-Montagne/Lurgi fluidized bed roaster is the industry standard.

The roaster product is leached with spent electrolyte (sulfuric acid) under near-neutral conditions to dissolve most of the zinc, copper, and cadmium, but little of the iron. The leach residue solids are releached in hot, strong acid to dissolve more zinc, since it attacks the otherwise insoluble zinc ferrites. The iron which is also dissolved in this second leach is then precipitated as jarosite, goethite, or hematite. The development of these iron precipitation techniques permitted the use of the hot, strong acid leach and an increase in zinc extraction from about 87% to greater than 95%. Simultaneously, the hot acid leach frequently generates a leach residue rich enough in lead and silver to provide significant byproduct value, as well as increased recovery of cadmium and copper.

The neutral solution is purified to remove impurities more noble than zinc, e.g., cadmium, copper, cobalt, nickel, arsenic, antimony, and germanium. The purification is accomplished by cementation in two or more steps with the addition of zinc dust. Generally, at least one cementation step is conducted at high temperature with arsenic, antimony, or copper-arsenic added. Cadmium is usually recovered in the metallic state and copper, nickel, and cobalt are recovered as sludges if present in sufficient quantities.

Zinc is extracted from the purified solution in cells using lead/silver alloy anodes and aluminum cathodes at a current density of 38–60 amperes/square foot (400–650 amperes/square meter). The product is normally SHG zinc, particularly if strontium carbonate is added and/or lead/silver anodes of greater than 0.596 silver content are used. After deposition of 24 to 72 hours, the cathodes are removed from the cells and the zinc is stripped by automatic machines in modern plants, melted, and cast for market. The move to automated handling of large cathodes was a major factor in lowering the overall labor requirement in producing zinc.

The following technical developments have led to the acceptance of the electrolytic process:

1. Adoption of high-capacity, low-labor fluidized-bed roasters
2. Adoption of continuous schemes for leaching and solution purification, allowing more automation and lower operating costs
3. Improved raw material utilization via hot acid leaching and iron precipitation as previously described
4. Construction of higher-capacity plants with larger equipment
5. Adoption of mechanized cathode handling/stripping with dramatically lower labor demands
6. Improved byproduct recovery via the hot acid leach.

With exception of leach residue (jarosite, goethite, etc.) disposal, the process is environmentally sound.

[1] Information for this topic furnished by C.O. Bounds, St. Joe Minerals Corporation, Monaca, Pennsylvania.

The electrolytic process is inherently a somewhat energy inefficient (being based on electrical rather than directly on fossil energy) and capital-intensive operation. A return to pyrometallurgical smelting is conceivable if the environmental concerns are addressed and a noncoke (or at least low-coke) process is developed. New hydrometallurgical developments include the near-commercial Sherritt-Gordon pressure leach to eliminate roasting and the generation of sulfur-dioxide-rich gases, and laboratory experiments with chloride-based leaching/electrolysis.

Production. Principal producers of slab zinc include the former U.S.S.R., Japan, Canada, the United States, Germany (West), Australia, Belgium, France, Poland, Italy, Spain, Mexico, and China. The first four countries mentioned account for well over half of the production. Countries with limited production include Finland, the Netherlands, the former Yugoslav Republics, Bulgaria, and North Korea.

Uses of Zinc

Some concept of the major uses for zinc can be gleaned from Table 1. Slab zinc is available in three grades, as specified by the American Society for Testing and Materials (Table 2).

Zinc Coating. Constituting the largest single use of the metal, zinc coating is accomplished mainly by dipping the product in molten zinc or by electroplating (electrogalvanizing). Hot-dip galvanizing employs chiefly the less pure grades of zinc. The life of galvanized material is proportional to the thickness of the coating, and recent developments in both electrogalvanizing and hot-dip galvanizing have been toward application of heavy coatings that will withstand deformation without peeling.

TABLE 1. CONSUMPTION OF SLAB ZINC IN THE UNITED STATES

Application of zinc	Percent of total tonnage consumed	
Galvanizing		40.8
Sheet and strip	26.5	
wire and wire rope	2.3	
tube and pipe	4.1	
fittings (tube and pipe)	0.6	
Tanks and containers	0.3	
structural shapes	0.3	
Fasteners	0.5	
pole-line hardware	0.4	
fencing, wire cloth and netting	1.5	
other	2.4	
In Brass and Bronze		13.8
Sheet, strip, and plate	6.6	
rod and wire	5.0	
tube	0.6	
casting and billets	0.2	
copper-base ingots	0.6	
Other copper-base products	0.8	
In Zinc-base Alloys		28.0
die casting alloy	27.4	
dies and rod alloy	0.1	
slush and sand casting alloy	0.5	
Other Uses		17.4
Rolled zinc	2.2	
zinc oxide	3.5	
other applications	11.7	
Total		100.0

TABLE 2. GRADES OF SLAB ZINC

Grade of zinc	Composition (Percent) Lead (maximum)	Iron (maximum)	Cadmium (maximum)	Zinc (minimum by difference)
Special High Grade	0.003	0.003	0.003	99.990
High Grade	0.03	0.02	0.02	99.90
Prime Western	1.4	0.05	0.20	98.0

Notes: When specified for use in manufacture of rolled zinc or brass, aluminum is held to 0.005% maximum.
Tin in Special High Grade zinc is held to 0.001% maximum.
Aluminum in Prime Western zinc is held to 0.05% maximum.
Source: American Society for Testing and Materials.

Because of its relatively high electropotential (position in the emf series of metals), zinc can provide electrolytic protection against corrosion of several common metals, notably products made of iron and steel. Advantage of this characteristic also is taken in the use of zinc as the anode material for a number of types of batteries, power packs, and fuel cells. In providing a protective coating over ferrous metals, the attack of corrosive materials on the zinc produces a relatively inert reaction-product film, which deters destruction of the underlying zinc and base metal. When the coating is broken, as may result from mechanical means such as scratching, abrading, etc., the zinc, having a higher electropotential than the ferrous metals, slowly is expended in furnishing the required protective current. Thus, serious corrosion is delayed for a long period, providing long useful life to the zinc-coated products except in the most adverse cases, or where a poor selection of construction materials was initially made.

The most widely used form of zinc coating is effected by hot-dip galvanizing in which steel sheets, coils, structurals, hardware, wire, and other forms are dipped in a bath of molten zinc. The zinc readily adheres to a previously cleaned (pickled and thoroughly washed) iron or steel surface. The thickness of the coating is controlled by manipulating process temperatures, time the underlying metals are in contact with the molten bath, and mechanical means used. Products that are commonly hot-dip galvanized include roofing, siding, transmission towers, highway guard-rails, light poles, culverts, and fencing. Other forms of zinc coating include flame-spraying or metallizing, flake galvanizing, sherardizing or cementation, plasma arc spraying, vacuum metallizing, and also painting with materials that contain zinc pigments.

Electrogalvanizing makes it possible to apply a zinc coating to such products as steel strip, wire, conduits, hardware, etc. in a high-speed fashion through electroplating. One-side zinc coating of steel sheet for automotive applications by electrodeposition is a notable innovation in recent years. One advantage of electroplating is that the products to be coated are not subject to thermal conditions that may alter dimensions and shape. Electrodeposits range in thickness from 0.00015 inch (0.004 millimeter) to 0.001 inch (0.25 millimeter). Sherardizing is accomplished by heating the ferrous materials to be coated at a temperature of about 350°C in contact with zinc dust in a closed vessel. The resulting coating consists of iron-zinc alloys. It has been found that sherardized coatings match the corrosion resistance of electrogalvanized or hot-dip coatings of equivalent thickness.

Die Castings. The major use of zinc as a structural material is in alloys for pressure die casting. Development of the modern zinc die-casting alloys was directly related to use of Special High Grade zinc, with the addition of particular alloying constituents held within close limits and control of impurities. For die castings it is essential to use this extra pure grade of zinc to ensure extremely low iron, lead, cadmium, and tin contents. It is also necessary to limit these same impurities in the metals added to make the desired zinc alloy composition. Only by such control can zinc die castings be produced that are stable in dimensions and properties.

The impurities lead, cadmium, and tin, if present in castings in amounts greater than the established maximums (0.005% lead; 0.004% cadmium; 0.003% tin), cause subsurface network corrosion. These limits are close to critical values. Iron is held to 0.10% maximum to prevent excessive skimming losses and machining problems.

Zinc alloys are low in cost of metal per casting, are easy to die cast, are cast at low temperatures, have greater strength than all other die-casting metals except the copper alloys, lend themselves to casting within close dimensional limits, permit the thinnest sections yet produced, and are machined at minimum cost. Their resistance to surface corrosion is adequate in a wide range of applications. Prolonged contact with moisture results in formation of white corrosion products, but surface treatments can be applied that largely prevent formation of such products.

Limiting service conditions for standard zinc-base die-casting alloys are as follows: At temperatures slightly above 95°C (200°F) their tensile strength is reduced 30% and their hardness 40%. At subzero temperatures, some embrittlement occurs, but impact strength is still in the same range as that of aluminum and magnesium die-casting alloys at normal service temperatures. At room temperature, impact strength of zinc die castings is much higher than that of aluminum or magnesium die castings or iron sand castings.

All die castings have at least a light flash at the die parting, and those requiring movable cores will have some flash around the cores. Flash is

also formed around ejector pins at the points at which they make contact with the casting.

Although it often is cheaper to cut threads than to cast them, for many pieces cast threads usually are more economical. Male threads usually are made with a parting parallel to the axis; this leaves a flash at the parting. The flash can be removed with a shaving tool in some instances, but in others a chasing operation is necessary.

Zinc die castings are invariably cast within quite close dimensional limits, but some machining is commonly required in addition to removal of flash, even though it may consist only of such simple operations as punching, drilling reaming, or tapping of holes. Zinc die castings can be soldered or welded, but ordinarily neither technique is used except for special applications or repair.

Many of the finishes applied to other types of metal products can also be applied to zinc die castings, although some differences in formulation as well as occasional differences in method of application may be desirable. The types of finishes applicable to zinc die castings include: mechanical finishes (buffed, polished, brushed, and tumbled); electrodeposited finishes (copper, nickel, chromium, brass, silver, and black nickel); chemical finishes (chromate, phosphate, molybdate and black nickel); and organic finishes (enamel, lacquer, paint and varnish, and plastic finishes). Electrodeposited coatings of virtually any metal capable of electrodeposition can be applied to zinc die castings.

The automotive industry uses by far the largest number of zinc alloy die castings. Zinc makes the average automobile last longer—17 pounds of zinc protect it from rust. Another 20 pounds are used to make zinc die cast parts like door handles, locks, carburetors, bodies for fuel pumps, windshield-wiper parts, speedometer frames, grilles, horns, heaters, parts for hydraulic brakes, and each tire contains about 1/2 pound of zinc, which is needed to cure rubber. The electrical industry probably uses a larger diversity of die castings than the automotive industry. Such parts are used in washing machines, oil burners, stokers, motor housings, vacuum cleaners, electric clocks, and kitchen equipment and utensils. Zinc die castings are used in business machines—typewriters, recording machines, picture projectors, vending machines, accounting machines, cash registers, cameras, slicing machines, garbage disposers, gasoline pumps, hoists, and drink mixers. Building hardware, padlocks, toys, and novelties also consume a substantial percentage of the total production of zinc-base die castings.

It is interesting to note that Gutenberg (1440s) used metal-based inks in printing the early Bibles. Zinc was used, along with copper and lead. These inks replaced those made of soot, which were prone to evanescence.

Much more detail on zinc metal products and applications will be found in the Horvick (1979) reference listed. Zinc alloys with copper are described under **Copper**.

Chemistry and Compounds

In virtually all of its compounds zinc exhibits the +2 oxidation state, although compounds of zinc(I) have been reported in the gaseous phase. Zinc is readily oxidized in the presence of hydroxide ions, e.g., by H_2O, this behavior being attributed to the stability of the $Zn(OH)_4{}^{2-}$ ion. Like other transition group 2 elements zinc has a marked tendency to form covalent structures, e.g., ZnO and ZnS.

Zinc oxide, formed by oxidation of the metal, dissolves in acids to yield Zn^{2+} ions, and in alkalies to form $Zr(OH)_4{}^{2-}$ ions. It reacts slowly with moist CO_2 to form the oxycarbonate, $5ZnO \cdot 2CO_2 \cdot 4H_2O$. Addition of an alkali metal hydroxide to a solution of a zinc salt does not precipitate the hydroxide, producing instead hydroxyzincate salt or a precipitate of flocculant zinc oxide. However, the hydroxide can be obtained from a sodium zincate solution on dilution and standing. Zinc hydroxide is amphiprotic, yielding Zn^{2+} ions with acids and $Zn(OH)_4{}^{2-}$ ions with (excess of) alkali hydroxides. Zinc peroxide is produced by treating a zinc chloride solution with sodium peroxide at a pH of 9.5. It is unstable, decomposing slowly on standing. Zinc oxide is used extensively in rubber, paints, and chemicals. Expanding uses include exterior latex paints, particularly alkyd-modified latex, the photocopy paper field, and as a substitute for mercury in mildew and fungus prevention formulations.

Unlike the other zinc halides, zinc fluoride, ZnF_2, is only slightly soluble in cold water. The anhydrous halides are prepared by direct union of the elements. In solution, zinc chloride, bromide, and iodide exhibit anomalous conductance properties attributed to undissociated molecules and complex ions. On heating these solutions, halogen acids, HX, are evolved, leaving oxyhalides in the fused residue. The zinc halides readily form double salts with halides of elements of main groups 1, 2, and sometimes 3 and 4. See also **Bromine**.

Zinc oxycarbonate is formed by the reaction of suspensions of the oxide or hydroxide with CO_2; to produce the normal carbonate, a very rapid stream of carbon dioxide and, usually, a somewhat higher pH is required.

Zinc also forms both nitrates and oxynitrates (in various hydrated forms) but the oxynitrate is less stable. It is formed by heating the hexanitrate, or treating the nitrate solution with NH_3.

Zinc forms a wide variety of other salts, many by reaction with the acids, though some can only be obtained by fusing the oxides together. The salts include arsenates (ortho, pyro, and meta), the borate, bromate, chlorate, chlorite, various chromates, cyanide, iodate, various periodates, permanganate, phosphates (ortho, pyro, meta, various double phosphates), the selenate, selenites, various silicates, fluosilicate, sulfate, sulfite, and thiocyanate.

Zinc sulfide, selenide, and telluride are more pronouncedly covalent than the oxide. They can be prepared from the elements, or in the case of first two, by the action of H_2S or hydrogen selenide upon zinc solutions. Zinc nitride, Zn_3N_2, prepared from zinc dust and NH_3, hydrolyzes readily to NH_3 and the oxide. Two zinc phosphides are known; Zn_3P_2, formed by heating the elements, yields phosphine with acids; ZnP_2 and ZnHP have also been prepared.

One of the features of the chemistry of zinc is the fact that it is among the elements having a large number of complex compounds, mostly with coordination numbers of four and tetrahedral, but some with coordination numbers of 6, such as those of ethylenediamine which contain the ion $[Zn(en)_3]_{2+}$. The large number of halogen double salts have already been cited. The marked donor ability of oxygen toward zinc is evident from the number of basic salts, the existence of the zincates (containing $ZnO_2{}^{2-}$ and also $Zn(OH)_4{}^{2-}$, the latter in strong alkali), and the formation of such chelate complexes as acetylacetonates and dioxalato complexes. Sulfur is a better donor than oxygen, so that addition compounds of the type $(R_2S)_2ZnX_2$ are formed from dialkyl sulfides and zinc halides, while thiourea forms chelate complexes containing $[Zn(th)^2]^{2+}$. The ready reactions with ammonia, as with amines, give large numbers of complexes; those with ammonia include diammines, triammines and tetrammines, containing $[Zn(NH_3)_2]^{2+}$, $[Zn(NH_3)_3]^{2+}$ and $[Zn(NH_3)_4]^{2+}$ respectively.

Prominent among the carbon donor complexes are the cyanides, principally compounds of $[Zn(CN)_4]^{2-}$, although $[Zn(CN)_3]^{-}$ is also known. Other carbon donor complexes are the triethyl and tetraethyl complexes, which are readily electrolyzed.

ZINC (In Biological Systems). Zinc was one of the first of the trace elements known to be essential for both plants and animals, and yet problems of zinc nutrition are still of pressing importance. Evidence of zinc deficiency in crops is being recognized in new areas and the use of zinc in fertilizers has increased steadily in recent years. A dry, cracked condition of the skin of pigs (*parakeratosis*) caused by a zinc-deficiency has been a problem to pork producers. Diseases and syndromes that have been attributed to zinc deficiency in the human diet include loss of appetite, loss of sense of taste, and delayed healing of burns and other wounds. It is interesting to note that application of zinc-containing ointments to promote healing is an old practice in human medicine. Laboratory animals deficient of zinc may be subject to serious reproductive problems, including infertility of males, failure of conception or implantation of the embryo, difficult births, and deformed offspring. The extent to which zinc deficiency is a primary cause of reproductive problems in farm animals and humans is not thoroughly understood, and research continues.

Patients of both sexes with sickle cell anemia have been reported to be zinc deficient. Administration of zinc to males with this disease has been shown to improve the hypogonadism and the short stature associated with this deficiency. Administration of small dosages of zinc sulfate is part of the therapy in treating certain types of sickle cell anemia. Zinc deficiency in crops is frequently observed where fields have been graded to smooth them so that irrigation water can be applied more uniformly. Where the topsoil is cut away from small areas of these fields, such crops as corn (maize) and beans may be stunted and many leaves will be white instead of the usual green. If zinc fertilizers, supplying as little as 10 pounds of zinc per acre (11.2 kilograms per hectare) are applied, bumper crops may be grown on these soils. Citrus trees are commonly fertilized with zinc.

When zinc fertilizers are used on soils deficient in zinc, crop production may be increased even though the zinc concentration in the plant tissues and especially in the seed show no increase. With higher levels of zinc fertilization, the zinc concentration in plants may increase. Some evidence shows that the value of food and feed crops as sources of dietary zinc can be improved by using zinc fertilizers at rates exceeding those required for optimal plant growth. However, very high rates of zinc fertilization can depress crop yields.

The zinc contained in plants is not fully utilized by animals. Diets high in calcium and phosphorus have been associated with poor digestibility of dietary zinc. Diets with large amounts of soy protein are particularly likely to require extra zinc fortification for livestock. Meat is an important source of zinc for human diets. Where supplementation of zinc is indicated, zinc sulfate, zinc oxide, and zinc carbonate are commonly used.

Zinc in Metabolism

Zinc was first recognized as a trace element—then referred to as a growth factor for Aspergillus niger—by Raulin (1869). Evidence for a specific biochemical role of zinc was first obtained by Keilin and Mann in 1940, when the metal was shown to be a stoichiometric component of bovine carbonic anhydrases. The findings of many other zinc-containing enzymes during the interim have indicated a diverse biological role for zinc.

The high affinity of zinc for nitrogeneous and sulfur-containing ligands seems chiefly responsible for the occurrence of zinc in a wide variety of biological compounds, such as proteins, amino acids, nucleic acids, and porphyrins. Operationally, the enzymes affected by zinc can be considered in two groups: (1) zinc metalloenzymes; and (2) zinc metal-enzyme complexes. Zinc metalloenzymes incorporate zinc so firmly in the protein matrix that they can generally be considered as an entity. Under reasonably mild conditions, the metal and protein moiety are isolated together and exhibit an integral stoichiometric relationship. On the same basis, a strict correlation is preserved between metal and enzyme activity, allowing the inferential identification of a specific biological function of zinc *in vivo*. Zinc metal-enzyme complexes, in contrast, comprise enzymes which are activated in vitro by the addition of zinc ions. The loose association and the relative lack of metal ion specificity render it difficult in many cases to assign specific biological significance to zinc *in vivo*.

In zinc metalloenzymes, zinc is a selective stoichiometric constituent and is essential for catalytic activity. It is frequently present in numerical correspondence with the number of active enzymatic sites, coenzyme binding sites, or enzyme subunits. Removal of zinc results in loss of activity. Inhibition by metal complexing agents is a characteristic feature of zinc metalloenzymes. However, no direct relationship holds between the inhibitory effectiveness of these agents and their affinity for ionic zinc. Although zinc is the only constituent of zinc metalloenzymes *in vivo*, it can be replaced by other metals in vitro, such as cobalt, nickel, iron, manganese, cadmium, mercury, and lead, as in the case of carboxy-peptidases.

Zinc is a ubiquitous component of animal and plant tissue. In vertebrates, most organs, including pancreas, contain 20–30 micrograms of zinc per gram of wet tissue. Liver, voluntary muscle, and bone hold about double this amount. Zinc contents ranging from 100 to 1000 micrograms/gram weight have been measured in islet tissues of certain teleost fishes. Correlation between zinc content and insulin storage suggest a parallelism, but evidence is wanting for zinc-insulin complexes *in vivo*. The highest zinc content determined among mammals is found in the *tapetium lucidum cellulosum* of adult for seals—up to 150,000 micrograms/gram. Human blood contains 7–8 micrograms zinc/milliliter. About 12% of this is present in serum, 3% in leukocytes, and 85% in erythrocytes. In these compartments, zinc occurs as part of zinc proteins and zinc metalloenzymes. In erythrocytes, zinc is correlated to carbonic anhydrase activity.

In 1991, B.C. Cunningham, M.J. Mulkerrin, and J.A. Wells (Genetech) reported that size-exclusion chromatography and sedimentation equilibrium studies demonstrated that zinc ion (Zn^{2+}) induced the dimerization of human growth hormone (HGH). Scatchard analysis of $^{65}An^{2+}$ binding to HGH shows that two ZN^{2+} ions are associated per dimer of HGH in a cooperative fashion. Cobalt (II) can substitute for Zn^{2+} in the hormone dimer and gives a visible spectrum characteristic of cobalt coordinated in a tetrahedral fashion by oxygen- and nitrogen-containing ligands. Human growth hormone is synthesized and secreted into storage granules before its release from the anterior pituitary.

In 1991, R.E. Klevit (University of Washington) reported on the recognition of DNA by Cys_2, His_2 zinc fingers. The "zinc finger" protein motif was so named because of the tandemly repeating pattern observed in the amino acid sequence of the transcription factor TFIIA. Klevit points out, "According to the original hypothesis, each 30-residue sequence is an independently folded unit that binds a zinc ion and is responsible for sequence-specific DNA binding."

Underwood (1977) reported that high levels of dietary zinc interfere with the normal absorption and metabolism of several minerals. Earlier, Stewart and Magee (1964) reported that experience with laboratory animals indicated that 7500 parts per million (ppm) zinc in a purified diet lowered the concentrations of calcium and phosphorus in bone. Other investigators showed that animals fed the same level of zinc were anemic and had deformed, fragile erythrocytes. The livers contained reduced amounts of ferritin and lower concentrations of iron in the ferritin. Whanger and Weswig (1971) showed that in rats fed 2000 and 4000 ppm zinc, liver copper concentration was decreased. The most sensitive responses to zinc have been obtained with animals receiving minimally required or suboptimal levels of copper Campbell and Mills, 1974; and Murthy et al., 1974). Based upon these earlier findings, Hamilton et al. (1979) investigated possible zinc interference with copper, iron, and manganese in young Japanese quail (*Coturnix coturnix japonica*). The objective of the investigators was to identify the minimal level of excess dietary zinc that would produce physiological and metabolic deviations from normal and to define some of the most sensitive zinc-mineral interactions. Because other workers had found a sensitive zinc-copper antagonism, the Hamilton

team studied the effects of supplemental zinc at copper levels of marginal deficiency. Data from the study showed that adequacy of copper intake is important when supplemental zinc is consumed either as a dietary supplement or in foods fortified with zinc. It was reported that results of the findings may be important for the general human population, whose dietary intake of many minerals, including copper, does not usually exceed the requirement or may be marginally deficient (Milne et al., 1978; Harland et al., 1978; Klevay, 1978). See also **Copper (In Biological Systems)**.

Zinc Poisoning: Soluble zinc salts are usually the etiologic agent in cases of zinc poisoning. The poisonous nature of zinc may be described as astringent, corrosive, and emetic. Sources of food poisoning include zinc-coated galvanized containers, pots, cans, tubs, and acids that convert zinc into soluble salts. Products that may be so involved include lemonade, cooked apples, mashed potatoes, spinach, chicken and tomatoes, and fruit punch. Zinc in combination with various organic and inorganic radicals (dimethyl dithiocarbamate, arsenate, etc.) can be quite poisonous.

ZINC BLENDE. See **Sphalerite Blende**.

ZINC CARBONATE. See **Smithsonite**.

ZINCITE. This mineral, (Zn, Mn)O, is an ore of zinc and occurs in considerable quantities at Franklin Furnace, New Jersey, where it is associated with willemite and franklinite. Its hexagonal crystals are rare, as it usually occurs massive, foliated, or in coarse to fine grains. When the crystals are observable, it reveals a perfect cleavage parallel to the base of the prism. The fracture is conchoidal. The mineral has a hardness of 4; specific gravity, 5.684; luster, subadamantine to vitreous; orange-yellow streak; color, red to orange-yellow; translucent to opaque. Zincite also has been found in Poland, Tuscany, Spain, Saxony, and Tasmania.

ZINC OXIDE PIGMENT. See **Paint and Finish Removers**.

ZINC PHOSPHATE COATINGS. See **Conversion Coatings**.

ZIRCON. This mineral is zirconium silicate, $ZrSiO_4$, and is the chief ore of zirconium. Zircon occurs in square tetragonal prisms, although sometimes it assumes pyramidal or irregular forms. The mineral may be found in some beach and river placer deposits, but generally it is associated as an accessory mineral in siliceous igneous rocks, crystalline limestones, schists, and gneisses—and in sedimentary rocks derived from the foregoing. Zircon is without good cleavage; is brittle, with a conchoidal fracture; hardness, 7.5; specific gravity, 3.7–4.7; luster, adamantine, brilliant; color, green, yellow-green, golden-yellow, red, red-brown, brown, and blue. The name zircon derives from an Arabic word *zarqun*, meaning vermilion, or perhaps from the old Persian *zargun*, meaning golden-colored.

Zircon occurs in the Ural Mountains; Trentino, Monte Somma, and Vesuvius, Italy; Arendal, Norway; Ceylon, India; Thailand; at the Kimberley mines, Republic of South Africa; Madagascar; and in Canada in Renfrew County, Ontario, and Grenville, Quebec. In the United States, zircon is found at Litchfield, Maine; Chesterfield, Massachusetts; in Essex, Orange, and St. Lawrence Counties, New York; Henderson County, North Carolina; the Pikes Peak district of Colorado; and Llano County, Texas.

Gem quality crystals from Ceylon (Sri Lanka) have been known for many years. They range from colorless to brownish orange, yellow, dark red, from light reddish-violet. Heat treated zircons provide a beautiful stone of light blue color. Colorless stones are used as a diamond substitute.

ZIRCONIUM. [CAS: 7440-67-7]. Chemical element symbol Zr, at. no. 40, at. wt. 91.22, periodic table group 4, mp 1,853°C, bp 4,376°C, density 6.44 g/cm^3, 6.47 g/cm^3 (single crystal). Metallic zirconium is allotropic. Up to about 863°C, the alpha phase (hexagonal close-packed) is stable; above this temperature, the metal assumes the beta phase (body-centered cubic). The most common impurity, oxygen, tends to stabilize the alpha phase.

Zirconium metal exhibits passivity in air due to the formation of adherent coatings of oxide or nitride. Even without the coating, it is resistant to the action of weak acids and acid salts, but dissolves in HCl (warm) or H_2SO_4 slowly, and more rapidly if F is present, forming compounds of ZrO^{2+} ions, or fluorozirconates in the last case.

Crystalline zirconium of high purity is a white, soft, ductile, and malleable metal, but that of 99% purity, when obtained at high temperature, is hard and brittle. Pure zirconium has a combination of properties which make it a valuable structural material for nuclear reactors. In addition to low neutron capture, zirconium has good strength at high temperatures, corrosion resistance to high velocity coolants, avoidance of formation of high activity isotopes, and resistance to mechanical damage from neutron radiation. Amorphous zirconium is a bluish-black powder. At about 500°C zirconium burns in air; heated in hydrogen forms hydride; heated in nitrogen a nitride; and heated in chlorine the tetrachloride. On the laboratory scale, zirconium metal may be produced by the reduction of the chloride, oxide, or potassium zirconium fluoride with sodium metal.

Zirconium was first identified by Klaproth in 1789. The first crude powder was made by Berzelius in 1824 by reducing potassium fluorozirconate with potassium. A sample with a purity of 98% was not produced until the 1950s. There are five natural isotopes ^{90}Zr through ^{92}Zr, ^{94}Zr, and ^{96}Zr. Six radioactive isotopes have been identified ^{87}Zr through ^{89}Zr, ^{93}Zr, ^{95}Zr, and ^{97}Zr. With exception of 93Zr with a half-life of 1.1×10^6 years, the half-lives of the other isotopes are expressed in minutes, hours, or days. Zirconium is ranked 19th in abundance of the chemical elements occurring in the earth's crust with an estimated average content of zirconium in igneous rocks of 0.026%.

First ionization potential 6.95 eV; second, 13.97 eV; third, 24.00 eV; fourth, 33.83 eV. Oxidation potentials $Zr + 2H_2O \longrightarrow ZrO_2 + 4H^+ + 4e^-$, 1.43 V; $Zr + 4OH^- \longrightarrow ZrO(OH)_2 + H_2O + 4e^-$, 2.32 V. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^2 5s^2$. Ionic radius Zr^{+4} 0.80 Å. Metallic radius 1.5895 Å. Other important physical properties of zirconium are given under **Chemical Elements**.

The most important ore for production of zirconium metal is zircon $ZrSiO_4$, which occurs in several regions in the form of a beach sand,

often mixed with silica, ilmenite, and rutile. A floating-dredge technique is used in the mining operation. Early phases of beneficiation often take place on the dredge. Nearly all of the silica is separated by means of spiral concentrators, with the ilmenite and rutile removed by magnetic and electrostatic separators. The purest concentrates are used for metal production; others for refractories. Direct chlorination of the ore is the most modern method of extraction. In a simple reaction, water-soluble zirconium tetrachloride is yielded. Liquid-liquid extraction in several stages is required for the removal of hafnium. With this process, zirconium containing less than 50 ppm hafnium can be produced. Ammonium thiocyanate is used to complex the zirconium while hafnium is extracted by a methyl ethyl ketone solvent. In a similar system, HNO_3 is used in the aqueous phase and tributyl phosphate as the solvent. After separation, the two metals are precipitated as their sulfates or hydroxides. Calcination yields a pure ZrO_2. For production of pure metal, the pure ZrO_2 is chlorinated to $ZrCl_4$. Sometimes this is sublimed for additional purification. The zirconium tetrachloride in the gaseous phase is reacted with molten magnesium, forming zirconium metal and magnesium chloride. There are several minor variations of these processes. For example, sodium may replace magnesium.

Uses

The most important application of zirconium is in the formulation of the base metal in an alloy of 98% zirconium, 1.5% tin, 0.35% iron-chromium-nickel, and 0.15% oxygen. This alloy is widely used in water-cooled nuclear reactors because of its excellent corrosion resistance up to about 350° in H_2O, and its low neutron cross section. Currently, about 90% of the zirconium produced is used for this application. The excellent corrosion resistance of zirconium to both strong acids and alkalis, particularly its resistance to strong caustic solutions at all concentrations and temperatures, is attracting increasing attention for application in chemical processing equipment. See also **Nuclear Power Technology**.

Chemistry and Compounds

Due to its $4d^25s^2$ electron configuration, zirconium forms tetravalent compounds readily, although the Zr^{4+} ion does not exist as such in aqueous solution, except at very low pH values, the common cation being hydrated ZrO^{2+} (or $Zr(OH)_2{}^{2+}$). Many of the tetravalent compounds are partly covalent. There are also less stable Zr(III) compounds. The remarkably close similarity in chemical properties to those of hafnium is due to the identical outer electron configuration ($5d^26s^2$ for Hf) and the almost identical ionic radii (Hf^{4+} is 0.86 Å) this relatively low value for Hf^{4+} being due to the lanthanide contraction.

Zirconium oxide, ZrO_2 is widely known, both as a mineral, baddeleyite, and as an industrial product obtained from zircon, $ZiSO_4$. Moreover, the precipitate obtained by action of alkali hydroxides upon solutions of tetravalent zirconium is a hydrated oxide. The latter is readily soluble in acids to form oxysalts, which are usually formulated in terms of the ZrO^{2+} ion, without including its water of hydration, e.g., as $ZrO(H_2PO_4)_2$. The hydrated ZrO^{2+} ion is not amphiprotic; it does not dissolve in alkali hydroxides. While it does react on alkali carbonate fusions, the compounds formed have been shown to be mixed oxides rather than zirconates.

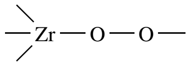
All four of the halides of zirconium and the common halogens are known and are solids at ordinary temperatures. They are readily hydrolyzed, to form hydrated oxyhalides such as $ZrOCl_2 \cdot 8H_2O$ or $ZrOBr_2 \cdot 8H_2O$. The tetraiodide yields both $ZrOI_2 \cdot 8H_2O$ and $ZrI(OH)_3 \cdot 3H_2O$, and this last composition probably represents best the structure of all these compounds. Like titanium tetrahalides, $ZrCl_4$ and $ZrBr_4$ act as Lewis Acids to form adducts, though of lesser stability, with H_2O and oxygen-function compounds, such as alcohols, ethers, and carboxy compounds generally. These include chelates formed with such compounds as 1,2-dihdroxy-benzene and acetylacetone, in which oxygen atoms act as electron donors. Zirconium also forms very stable complexes with $POCl_3$.

The trihalides of zirconium, like the dihalides of titanium, are extremely strong reducing agents, reacting even with H_2O.

Zirconium nitride, Zr_3N_4, is made by ammoniating the tetrachloride to yield $Zr(NH_3)4Cl_4$, which yields the nitride on heating. The nitride, like the boride and carbide, are alloy-like in character, with high fusing points, extreme hardness, and subject to considerable variation in composition. Thus Zr_3N_4 may vary in composition to ZrN without material change in its properties.

Unlike titanium, zirconium forms a few normal tetravalent salts, such as a tetranitrate and a tetrasulfate, as well as its more common basic salts. However, the normal salts readily undergo hydrolysis to form the basic salts.

Like titanium, zirconium forms halogen complexes, the most stable of which is the hexafluoride, $ZrF_6{}^{2-}$, as well as $ZrCl_6{}^{2-}$, and $ZrBr_6{}^{2-}$, which are less stable, except in concentrated solutions of the hydrogen halides. Zirconium also forms stable peroxy complexes, containing



Unlike titanium, zirconium forms a heptafluoride ion, $ZrF_7{}^{3-}$, which is quite stable.

ZOISITE. This mineral is a hydrous aluminum silicate corresponding to the formula $Ca_2Al_3(Si_3O_{12})(OH)$, crystallizing in the orthorhombic system. Clinozoisite (monoclinic) is its isomorphous counterpart. Zoisite occurs as prismatic crystals, usually deeply striated vertically, and as compact or columnar masses. Perfect prismatic cleavage; brittle; uneven to conchoidal fracture; hardness, 6.5–7; specific gravity, 3.355; luster, vitreous to pearly; transparent to translucent; color, grayish white, green, pink (the manganese-rich variety, thulite), and blue to purple (tanzanite).

Zoisite occurs in crystalline schists which are products of regional metamorphism of basic igneous rocks rich in plagioclase, the calcium-rich feldspar; also in argillaceous calcareous sandstones, thulite from quartz veins, pegmatites, and metamorphosed impure limestones and dolomites.

Tanzanite is the blue to purple variety of zoisite and represents a recent discovery of this heretofore unknown variety from Tanzania. It occurs here as excellent transparent crystals from which fine gems have been cut.

ZONE REFINING. One of a class of techniques known as fractional solidification, in which a separation is brought about by crystallization of a melt without solvent being added. See also **Crystallization**. A massive solid is formed slowly and a sizable temperature gradient is imposed at the solid—liquid interface.

Zone refining can be applied to the purification of almost every type of substance that can be melted and solidified, e.g., elements, organic compounds, and inorganic compounds. Because the solid—liquid phase equilibria are not favorable for all impurities, zone refining often is combined with other techniques to achieve ultrahigh purity.

Because of the high costs of zone refining its application thus far have been limited to laboratory reagents and valuable chemicals such as electronic materials. The cost arises primarily from the low

processing rates, handling, and high energy consumption owing to the large temperature gradients needed.

ZSIGMONDY REAGENT. A reagent for colloids which is a red colloidal solution of metallic gold obtained by reducing auric chloride by formaldehyde in the presence of an alkali. When mixed with sodium chloride, this reagent becomes blue because of an agglomeration of the particles of gold, but this color change is prevented by the presence of an adequate amount of certain other colloids. They can be classified according to the amount required to prevent the color change.

ZSIGMONDY, RICHARD (1865–1929). A native of Austria, Zsigmondy received the Nobel prize in chemistry in 1925 for his demonstration of the heterogeneous nature of colloid solutions and for the methods he used, which have since become fundamental in modern colloid chemistry. His most important contribution to chemistry was his invention of the ultramicroscope (with Siedentoph) in 1903.

See also **Tyndall Effect**; and **Ultramicroscope**.

ZWITTERION. An ion carrying charges of opposite sign, which thus constitutes an electrically neutral molecule with a dipole moment; looking like a positive ion at one end and a negative ion at the other. Most aliphatic amino acids form such dipolar ions, hence react with both strong acids and strong bases.

ZYMOLYTIC REACTION. A chemical reaction catalyzed by an enzyme, especially a reaction involving bond rupture or splitting, usually a hydrolysis.

Coagulation (Hofmeister series), **389**
Coal, **389-400**
excess air for combustion, 426t
revegetation after mining, 1439-1440
Coal conversion (Clean Coal) processes, **400-406**
Coal-tar analgesics, 92-93
Coal tar-creosote, wood preservative, 1752
Coarse vacuum, 1661t
Coar tar and derivatives, **406-409**
Coated abrasives, 2
Coating agents (Foods), **409**
Coatings, **1196-1203**
CoA-transferases, 571t
Cobalamin, 1701-1703
Cobalt
abundance, 330t, 1132t
biologically active chelates, 323t
constituent of human plasma or serum, 244t
corrosion resistant alloys, 446t
covalent radius, 344t
electronic structure, 336t
interatomic distance, 342t
ionic crystal radius, 341t
major sources of industrial minerals, 1011t
nuclides (isotopes and isobars), 331t
physical properties of high temperature, 774t
principal characteristics, 327t
trace mineral nutrient, 1002t, 1005
Cobalt [CAS: 7440-48-4], **409-412**
Cobaltiferous pyrite, cobalt source, 410t
Cobalt (In Biological Systems), **412**
Cobaltite, **412**
Cobalt-nickel, thin-film applications, 958t
Cobalt-nickel-phosphorus, thin-film applications, 958t
Cobalt oxide, colorant for glass, 725t
Cobalt-phosphorus, thin-film applications, 958t
Cobalt superalloys, 776
Cocaine, 49t, 50
Coconut oil, 1671
characteristics and properties, 1672-1673t
higher alcohol manufacture from, 47
Codamine, 49t
Codeine, 49t, 50, 91, 1041
Coenzymes, **412-415**
Coir, 632t
Coke-oven gas, excess air for combustion, 426t
Colchicine, 50-51
Cold-cathode ionization vacuum gage, 1664
Cold fusion, 699
Cold-rolled steel, magnetic properties, 955t
Cold-worked steel, **415**
Colemanite, **415**
Colistin, activity and producing organism, 128t
Collagen, **415**
Collagen abnormalities, genetic influence, 716
Collagenase, therapeutic enzyme, 574t
Colloid chemistry, **415**
Colloid systems, **415-419**
Color, quarks, 1397
Color addition, 31-32
Colorants (Food), **419-420**
Color centers, **420**
Color-difference meter, 1295
Colored glass, 725-726
Color film, 1291-1292
Colorimeter, 1295
Colorimetry, **420**
Colour Index (CI), 512, 527
Columbite, **420**
Columbium
abundance, 330t
corrosion resistant alloys, 446t
Combined sewers, 1724
Combing wools, 1752
Combustion, in microgravity, 741
Combustion (Fuels), **420-427**
Common ion effect, **427**
Comparative biology, **427**
Compet, 623t
Complex compound, 428
Composite materials, **427**
Composting, 205t
Compound (Chemical), **427-429**
Comprehensive Environmental Response, Compensation, and Liability Act (Superfund), 1711t
Compression (gas), **429-430**
Compton effect, gamma rays from, 704
Computational chemistry, **430**
Computer-assisted molecular modeling (CAMM), 1028
Computer graphics, molecular modeling application, 1028
Computerized tomography (CT), 1761-1762
Computional methods, for molecular modeling, 1028-1029
Conalbumin, source and function, 986t
Conant, James Bryant (1893-1978), **430**
Concentration (Chemical), **430**
Concentration (Process), **430-431**
Concrete, **431**
Condensate, **431**
Condensation, yeast participation, 1769t
Condensation compound, 428
Condensation curve, **249**
Condensation polymerization, 1181
Condensing enzyme, 282t
Conduction heat transfer, 758-759
Congenital adrenal plasia, genetic influence, 716
Coniferin, 734t
Coniine, 49t
Conjugate acid, 12
Conjugate base, 12
Conjugated double bonds, 346
Connate water, **431-432**
Conservation laws and symmetry, **432-434**
Consolute liquids, **434**
Consolute temperature, **434**
Constantan, thermal conductivity, 758t
Constituent, **434**
Constructed wetland, 205t
Contact angle, 1584
Contact potential difference, **435**
Contractile proteins, **434-435**, 1374
Contractility, **434-435**
Convection, **435**
Convection heat transfer, 759
Conversion, **435**
Conversion coatings, **435-436**
Conversion ratio, **436**
Coolant, **436**
Coordination compounds, **437**
Coordination number, **437**
Coordination polyhedra, **437**
Copaline, **437**
Copalite, **437**
Copper
abundance, 330t, 1132t
amount in pure irons, 877t
biologically active chelates, 323t
constituent of human plasma or serum, 244t
corrosion resistant alloys, 446t
crystal structure, 455
density, 474t
electronic structure, 336t
EPA pretreatment standard for aqueous discharge, 985t
hardness of cold-rolled, 755t
interatomic distance, 342t
ionic crystal radius, 341t
major sources of industrial minerals, 1011t
modulus and rigidity, 538t
nuclides (isotopes and isobars), 331t
plant micronutrient, 613t
plant micronutrient deficiencies, soils of U.S., 616t
principal characteristics, 327t
purification, 863t
residence time in sea water, 1133t

standard electrode potential, 31t
thermal conductivity, 758t
trace mineral nutrient, 1002t, 1004
Copper acetate, 6
Copper alloys, 58
Copper-cadmium cells, 186t
Copper carbonate, 441
Copper [CAS: 7440-50-8], **437–441**
Copper chromate, wood preservative, 1752
Copper-constantan thermocouples, temperature range, 1605t
Copper glance, 321
Copper (In Biological Systems), **442–443**
Copper-lead cells, 186t
Copper-zinc cells, rechargeable, 186t
Coquimbite, abrasion pH, 1t
Corbino effect, 752
Cordierite, **443**
Corey, Elias James (1928–), **443**
Cork, **443**
density, 474t
Corn, susceptibility to iron deficiency, 874t
Cornforth, John (1917–), **443**
Cornmint oil, 647t
Corn oil, 1671
Corrosion, **443–446**
Corrosion embrittlement, **446**
Corrosion resistant alloys, 446t
Corsite, **446**
Corticosteroids, 35
Corticosterone, 35
Cortisol, 35
commercial microbial transformations used to produce, 1550t
where produced, structure, and principal functions, 786t
Cortisone, 35, 93
Corttrell, Frederick G. (1877–1948), **447**
Corundum, **446**, 708
abrasive properties, 745t
hardness, 2t, 755t, 1008t
heat effect, 708t
irradiation, 709t
Corynebacterium diphtheriae, gram-positive, 168t
Cosmegen, DNA interactive agent, 357t
Cotton, **446**, 632t
fiber-dye property requirements, 521t
generic designation and definition, 624t
physical properties of staple, 626t
susceptibility to iron deficiency, 874t
Cottonseed oil, 1671
characteristics and properties, 1672–1673t
good source of protein, 1373
Coulomb (C), 1643t
Coulometer, **446–447**
Coupling, 1180
Coupling (Chamical), **447**
Covalent bonds, 345–346
Covalent compound, 428
Covellite, **447**
CPT-11, topoisomerase interactive, 357t
Cracking, 1179
Cram, Donald Jmaes, **449**
Creatine kinase, target of medical diagnostic test, 975t
Creatinine
in 24 hour urine sample, 1657t
target of medical diagnostic test, 975t
Creep (Metals), **449–450**
Creking process, **447–449**
Cresex process, 41t
Creslan, 621t
Creutzfeld-Jakob disease, 1696
Crick, Francis Harry Compton (1916–), **449–450**
Crin vegetal, 632t
Cristobalite, crystal structure, 455
Critical composition, **450**
Critical concentration, **450**
Critical density, **450**
Critical humidity, 793
Critical mass, **450**, 1102
Critical point, **450**
Critical solution temperature, **450**
Critical temperature, **450**
Critical volume, **450**
Crocidolite, 149–150
physical and chemical properties, 150t
Crocidolite (Blue asbestos), **451**
Crocoite, **451**
Crospovidones, 1680
Crotonylene, 55
Crucible, **451**
Crude oil pipelines, 1259–1260
Cryochemistry, **451**
Cryogenic materials, **451**
Cryogenic pumping, 1663
Cryogenics, **451–452**
Cryohydrate, **452**
Cryohydric point, **452**
Cryolite, **452–453**
Cryopump, **453**
Cryoscope, **453**
Cryoscopic constant, **453**
Cryotron, **453**
Cryptococcus neoformans, 1769
Cryptocrystalline, **453**
Cryptopine, 49t
Cryptopine alkaloids, 49t
Crystal, **453–459**
Crystal (Homometric Pairs), **461**
Crystal (Isomorphous), **461**
Crystal (Mixed), **461**
Crystal field theory, **459–461**
Crystal habit, **461**, 751
Crystal lattice energy, 921
Crystallization, **461–462**
Crystal oscillator, **461–462**
Crystal phases, **462**
Crystal pickup, **462**
CT metal, antimony content, 139t
Cubic boron nitride
abrasive properties, 745t
hardness, 2t
Cubic crystal system, crystallographic elements, 455t
Cubic zirconia, 708
Cummingtonite, **462**
Cumulative excitation, **462**
α-Cumyl hydroperoxide, physical properties, 1231t
tert-Cumyl peroxyacetate, properties, 1239t
tert-Cumyl peroxybenzoate, properties, 1239t
tert-Cumyl peroxypivalate, properties, 1239t
Cunico I, thin-film applications, 958t
Cunico II, thin-film applications, 958t
Cunife I, thin-film applications, 958t
Cunife II, thin-film applications, 958t
Cupric acetate, 441
Cupric acetoarsenite, 441
Cupric acid orthoarsenite, 441
Cupric chloride, 441
Cupric hydroxide, 441
Cupric oxide, 441
Cupric sulfate, 441
Cuprite, **462**
crystal structure, 455
Cupronickels, 440t
Cuprous acetylide, 8
Cuprous cyanide, 441
Cuprous iodide, 441
Cuprous oxide, 441
colorant for glass, 725t
Curie, Marie (1867–1934), **462**
Curie, Pierre (1859–1906), **462**
Curie (Ci), 1643t
Curie point, **462**
Curie temperature, **462**
Curie-Weiss law, **462**
Curium, 23t
binary compound properties, 25–26t
electronic structure, 337t
interatomic distance, 342t
ionic crystal radius, 341t
oxidation state, 24t
physical properties, 24t
principal characteristics, 327t
Curium [CAS: 7440-51-9], **462–463**
Curl, Robert F., Jr. (1933–), **463**
Cut rubber thread, 631
physical properties, 631t
Cyamelide, 464
Cyanamide [CAS: 420-04-2], 464
Cyanamides, **464**
Cyanazine, environmental health advisories, 771t
Cyanic acid and related compounds, **464**
Cyanin, 734t
Cyanoacetic acid, 964
Cyanoacrylates, monomer reactivity and suitable initiator for, 838t
2-Cyanoacrylic ester polymers, 18–19
Cyanocobalamin, 1701
Cyanogen [CAS: 460-19-5], **465**
Cyanohydrins, 48, **465**, 899
Cyanuric acid, 464
Cybotaxis, **466**
Cycle (c), 1643t
Cycle oils, 1255
Cycle per second (Hz, c/s), 1643t
Cyclic compound, 428
Cyclic imines, 820–821
Cycloheptanone, physical properties, 900t
2,5-Cyclohexadiene-1,4-dione, 1401
Cyclohexane diisocyanate (CHDI), 1654
Cyclohexanol, 47, **466**
Cyclohexanone, **466**
physical properties, 900t
Cyclohexanone cyanohydrin, 465t
Cyclohexasilanyl, 1477
Cyclohexyl acrylate, physical properties of polymers, 18t
Cyclohexyl hydroperoxide, physical properties, 1231t
Cyclo-ligases, 571t
Cycloolefins, polymerization, 1149
Cyclopentane, in Texas natural gas, 1054t
Cyclopentanone, physical properties, 900t
Cyclopentanoperhydrophenanthrene, 35
Cyclophosphamide USP, DNA alkylating/cross-linking agent, 356t
Cyclopropane, 100t
Cyclosilicate minerals, 1013
Cyclosporin A, activity and producing organism, 128t
Cyclosporine, activity and producing organism, 128t
Cyclotron, **466**
Cymex process, 41t
Cysteine
first isolation and isoelectric point, 77t

Cysteine (*continued*)
manufacture, 76t
structural classification, 79t
Cystine
first isolation and isoelectric point, 77t
manufacture, 76t
production, 80
in selected foods, 75t
structural classification, 79t
Cystinuria, genetic influence, 716
Cytarabine USP, antimetabolite, 355t
Cytochrome *c*, 466–467
Cytochrome oxidase, 466–467
Cytochromes, **466–467**
metal chelate enzyme, 323t
Cytogenetics, 711
Cytology, 711
Cytosar, antimetabolite, 355t
Cytotoxic chemicals, **467**
Cytoxan, DNA alkylating/cross-linking agent, 356t

D

Dacarbazine USP, DNA alkylating/cross-linking agent, 356t
Dacite, **469**
Dacron, 623t
Dactinomycin, activity and producing organism, 128t
Dactinomycin USP, DNA interactive agent, 357t
Daguerreotype, 1289
Dairy mold, 1770
Dalapon, environmental health advisories, 771t
Dalbaheptide antibiotics (glycopeptides), **117–119**
Dalton, John (1766–1844), **469**
Dalton law, **469**
Danburite, **469**
Daptomycin, activity and producing organism, 128t
Darcy (D), 1643t
Darcy's law, **469**
Darmstadtium, 24, 334
electronic structure, 337t
principal characteristics, 328t
Darvon, 93t
Datolite, **469**
Daturine, 49
Daughter element, **470**
Daunorubicin hydrochloride USP, DNA interactive agent, 357t
Davy, Sir Humphrey (1778–1829), **469**
Day (d), 1643t
DCPA, environmental health advisories, 771t
2,4-D (2,4-Dichlorophenoxyacetic acid), in hazardous waste, 1711t
Deacon process, **469**
Dealkylation, catalyst application, 305
Deaminase, therapeutic enzyme, 574t
Deamination, yeast participation, 1769t
Deaeration, **469**
De Broglie, Louis-Victor (1892–1987), **469–470**
De Broglie wavelength, **470**
Debye, Peter J. W. (1884–1966), **470**
Debye-Falkenhagen effect, **470**
Debye-Hückel limiting law, **470**
Debye-Sears effect, **470**
Debye theory of specific heat, **470**
Deca, 1643t
Decabromo-diphenyl oxide, flame retardant, 640t
Decanedioic acid, physical properties, 490t
Decaplanin, producing organism, 118t
Decarboxylation, yeast participation, 1769t
Decarburization, **470**
Decay product, **470**
1-Decene, physical properties, 1150t
Deci, 1643t
Declomycin, year of discovery, 130t
Decolorizing agents, **470–471**
Decomposition (Chemical), **471**
Deep inelastic scattering, 333
Deepwater oil production, 1252
Defoaming agents, **471**
Degasification, **471**
Degassed water, 1722
Degeneracy, **471**
Degradation (Chemical), **471–472**
Degree Celsius (C), 1643t
Degree Fahrenheit (F), 1643t
Degree Rankine (R), 1643t
Degrees of freedom, **679**
Dehumidification, **472**
Dehydration (Chemical), **472**
Dehydrochlorination, 1180
Dehydrocyclization, catalyst application, 304t
Dehydrogenation, **472**, 1180
catalyst application, 304t, 305
Dehydroisoandrosterone, 98
Deionizing, **472**
Deisenhofer, Johann (1943–), **472**
Deliquescence, **472–473**
Delphinin, 734t
Demal solution, **473**
Demantoid, 705
Demeclocycline, year of discovery, 130t
Demerol, 93t
N-Demethylefrotomycin, formula and producing organism, 116t
N-Demethyl-vancomycin, producing organism, 118t
Demineralization, **473**
Demulsification, **473**
Dendrite, **473**
Dengue vaccine, 1660
Dengue virus, 1694
Dense glass, 1163t
Densitometer, 1295
Density, **473–474**
Deodorizing, oils, 1671
Deoxidized copper, 438t
Deoxidizing agent, **474**
Deoxyribonuclease
metal chelate enzyme, 323t
therapeutic enzyme, 574t
Deoxyribonucleic acid (DNA), **474**, 712–713
structure, 1125
Dephlegmation, **475**
Depo-provera, hormonal therapy, 358t
Deptomycin, activity and producing organism, 128t
Derivative (Chemical), **475**
Derived units, 1642t
Derwent world patents index, 769t
Desalination, **475–478**, 1735
Desflurane, 100t
Desorption, **478**
Desoxycorticosterone, 35
Destruxin B, activity and producing organism, 128t
Detergents, **478–481**
Deuterium, **481–482**
Deuteron, **482**
Devitrification, **482**
Dew point, **482**
Dexamethasone, 93
Dextrins, use in food processing, 671t
Dextrorotatory, 78, 1543
Dextrose, purification, 863t
Dezincification, **482**
Dhurrin, 734t
Diabetes, possible viral roles, 1696
Diabetes mellitus, genetic influence, 716
Diacetone alcohol, 7
physical properties, 900t
Diacetoneamine, 7
Diacetyl
as key odor/tase compound, 649
physical properties, 900t
Diacetylmorphine, 51
Diacetyl peroxide, properties, 1237t
Diacyl peroxides, organic peroxide initiators, 841t
Diafiltration, 1636
Diagenesis, **482**
Di-*tert*-alkyl peroxides, organic peroxide initiators, 841t
Dialkyl peroxydicarbonates, organic peroxide initiators, 841t
Di(*tert*-alkylperoxy)ketals, organic peroxide initiators, 841t
Diallage, **482**
Diallyl phthalate, dye carrier, 512t
Dialysis, **482**
Diamagnetism, **482**
Diamines and higher amines, aliphatic, **482–484**
1,3-Diaminopropane, physical properties, 483t
Diammonium phosphate, 87–88
in water-soluble flame retardant formulation, 642t
Diammonium sodium cobaltinitrite, 86
Diamond, **484–486**, 708, 1009t
abrasive properties, 745t
absolute index, 1426t
crystal structure, 455
hardness, 2t, 755t
heat effect, 708t
irradiation, 709t
Diamond anvil high pressure cell, **486–488**
Diamond Pyramid hardness, 756
Di-*tert*-amyl peroxide, physical properties, 1232t
2,2-Di(*t*-amylperoxy)propane, boiling point, 1234t
Dianthrol, 105
Dianthrone, 105
Diaphragm cell, **489**
Diaryl ketones, 899
Diaspore, **489**
Diastovaricins, biological activity, 108t
Diatomaceous earth, hardness, 1008t
Diatomaceous silica, insulation material, 856t, 857
Diatomic gases, 334
Diatomite, **489–490**
abrasive properties, 745t
Diazo compound, 1169t
Diazo compounds, **165–166**
Dibasic acids, 13
Di(benzenesulfonyl) peroxide, properties, 1237t
Di(benzocyclobutene-4-carbonyl) peroxide, properties, 1237t
Dibenzoyl peroxide, properties, 1237t
Dibenzyl peroxydicarbonate, properties, 1237t
Dibromo-ethyldibromocyclohexane, flame retardant, 640t
Di(4-*tert*-butylcyclohexyl) peroxydicarbonate, properties, 1237t
Di-*tert*-butyl diperoxyadipate, properties, 1239t
Di-*tert*-butyl diperoxycarbonate, properties, 1239t
Di-*tert*-butyl diperoxyoxalate, properties, 1239t
Di-*tert*-butyl diperoxyphthalate, properties, 1239t
Di-*tert*-butyl peroxide, physical properties, 1232t

2,2-Di(*t*-butylperoxy)butane, boiling point, 1234t
1,1-Di(*t*-butylperoxy)cyclohexane, boiling point, 1234t
Dibutyl peroxydicarbonate, properties, 1237t
Di-*sec*-butyl peroxydicarbonate, properties, 1237t
1,4-Di(2-*tert*-butylperoxyisopropyl)benzene, physical properties, 1232t
2,2-Di(*t*-butylperoxy)propane, boiling point, 1234t
Dibutyl phthalate, physical properties, 585t
Dicalcium phosphate dihydrate, properties of leavening acid, 925t
Dicamba, environmental health advisories, 771t
Di(2-carboxybenzoyl) peroxide, properties, 1237t
Di(4-carboxybutyryl) peroxide, properties, 1237t
Dicarboxylic acids, **490–491**
Di(3-carboxypropionyl) peroxide, properties, 1237t
Dichlobenil, environmental health advisories, 771t
Di(chloroacetyl) peroxide, properties, 1237t
m-Dichlorobenzene, physical properties, 366t
o-Dichlorobenzene
  dye carrier, 512t
  physical properties, 366t
p-Dichlorobenzene, physical properties, 366t
2,5-Dichloro-1,4-benzoquinone, physical properties, 1402t
Di(4-chlorobenzoyl) peroxide, properties, 1237t
1,3-Dichloro-cis-2-butene, 1749
2,3-Dichloro-5,6-dicyano-1,4-benzoquinone, physical properties, 1402t
2,3-Dichloro-1,4-naphthoquinone, physical properties, 1402t
Dichromates, 382–383
Dicinnamoyl peroxide, properties, 1237t
Diclofenac, 93t
Dictamine, 49t
Dicumyl peroxide, physical properties, 1232t
Di(cyclohexylcarbonyl) peroxide, properties, 1237t
Dicyclohexyl peroxydicarbonate, properties, 1237t
Didecanoyl peroxide, properties, 1237t
Didodecanoyl peroxide, properties, 1237t
Didodecyl peroxydicarbonate, properties, 1237t
Die, **491**
Die casting, **491**
Dieldrin, definitely established workplace carcinogen, 297t
Dielectric heating, **491–492**
Dielectric theory, **492–493**
Diels, Otto P. H. (1876–1954), **493**
Diels-Alder reaction, 48, **493**, 1177
Dienes, monomer reactivity and suitable initiator for, 838t
Diesel fuel, in representative U.S. crude oils, 1242t
Dietary fiber, **617**
Diethanolamine, 587
Diethoxyaluminum *tert*-cumyl peroxide, physical properties, 1232t
Diethyl adipate, physical properties, 585t
Diethyl carbonate, physical properties, 585t
3,6-Diethyl-3,6-dimethyl-1,2,4,5-tetroxane, 1234t
Diethylene glycol, physical properties, 590t
Diethyleneglycol-bis(allylcarbonate), 60
Diethylene glycol monostearate, as release agent, 1435t
Diethylenetriamine, physical properties, 483t
Diethylenetriamine adduct, commercial polyether polyol, 1654t
Di(2-ethylhexyl) adipate, physical properties, 585t
Di(2-ethylhexyl) peroxydicarbonate, properties, 1237t
Di(2-ethylhexyl) phthalate, physical properties, 585t
Diethyl ketone, physical properties, 900t
Diethyl malonate [CAS: 105-53-3], 963
Diethylnitrosamine, 1082
Diethyl peroxide, physical properties, 1232t
Diethyl peroxydicarbonate, properties, 1237t
Diethyl phthalate
  dye carrier, 512t
  physical properties, 585t
Diethylstilbestrol diphosphate USP, hormonal therapy, 358t
Diffraction, **493**
Diffraction grating, **494**
Diffusion, **494–495**
Diffusion current, **495**
Diffusion potential, **495**
Diffusion pumps, 1663
Diflunisal, 93t
Di(2-furanylcarbonyl) peroxide, properties, 1237t
Digester, 205t
Digester (Process), **495**
Digesters, for wood pulp, 1380–1381
Digestion, **495**
Digipurpurin, 735
Digitalin, 734t
Digitalis, **495**, 735
Digital subtraction angiography, 1763
Digitonin, 734t, 735
Digitoxin, 734t
Diheptanoyl peroxide, properties, 1237t
Dihexadecanoyl peroxide, properties, 1237t
Dihexadecyl peroxydicarbonate, properties, 1237t
Dihydric alcohols, 46
9,10-Dihydro-9,10-epidi-oxyanthracene, physical properties, 1232t
Dihydrofollicular hormone, where produced, structure, and principal functions, 787t
Dihydrofolliculin, where produced, structure, and principal functions, 787t
Di(hydrogenated tallow)alkyldimethylammonium chloride, 1398
Dihydromocimycin, formula and producing organism, 116t
Di(2-hydroperoxy-2-butyl) peroxide, 1234t
1,1-Dihydroperoxycyclododecane, 1234t
Di(1-hydroperoxycyclohexyl) peroxide, 1234t
Dihydrotheelin, where produced, structure, and principal functions, 787t
Dihydroxyacetone phosphate, 283
Di(1-hydroxycyclohexyl) peroxide, 1234t
3,5-Dihydroxy-3,5-dimethyl-1,2-dioxolane, 1234t
Di(1-hydroxyethyl) peroxide, 1233t
Di(hydroxymethyl) peroxide, 1233t
Di(1-hydroxynonyl) peroxide, 1233t
Di(1-hydroxyoctyl) peroxide, 1233t
Di(1-hydroxypentyl) peroxide, 1233t
Dihydroxy-phenylalanine, manufacture, 76t
Di(isobornyl) peroxydicarbonate, properties, 1237t
Diisobutyl ketone, physical properties, 900t
Diisobutyryl peroxide, properties, 1237t
p-Diisopropylbenzene dihydroperoxide, physical properties, 1231t
p-Diisopropylbenzene mono-hydropero, physical properties, 1231t xide
Diisopropyl ketone, physical properties, 900t
Diisopropyl malonate, 963
Diisopropyl peroxide, physical properties, 1232t
Diisopropyl peroxydicarbonate, properties, 1237t
Diketene, 899
Dilatancy, **495**
Dilation number, **495**
Dilatometer, **495**
Diluent, **495**
Dimer acids, **495–496**
  monomer for nylon resins, 1333t
Di(methanesulfonyl) peroxide, properties, 1237t
Dimethyl adipate, physical properties, 585t
Dimethylallylamine, 60
Dimethylaminoethyl methacrylate, copolymers with PVP, 1682
2-Dimethylaminoethyl methacrylate, physical properties, 988t
Dimethylaminopropylamine, physical properties, 483t
Dimethyl-2,2′-azobis-[2-methylpropionate], commercial azo initiator, 841t
Dimethylbenzenes, 1763, 1764–1765
2,5-Dimethyl-1,4-benzoquinone, physical properties, 1402t
Di(2-methylbenzoyl) peroxide, properties, 1237t
cis-1,4-(2,3-Dimethyl butadiene), melting range, 1546t
trans-1,4-(2,3-Dimethyl butadiene), melting range, 1546t
3,3-Dimethyl-2-butanone, physical properties, 900t
Dimethyl carbonate, physical properties, 585t
2,5-Dimethyl-2,5-di(benzoyl-peroxy)-hexane, properties, 1239t
2,5-Dimethyl-2,5-di(*tert*-butyl-peroxy) hexane, physical properties, 1232t
2,5-Dimethyl-2,5-di(*tert*-butylperoxy)-3-hexyne, physical properties, 1232t
2,5-Dimethyl-2,5-dihydroperoxyhexane, physical properties, 1231t
2,5-Dimethyl-2,5-dihydroperoxy-3-hexyne, physical properties, 1231t
1,1-Dimethylethylnitrate, 1082
1,1-Dimethylethyl nitrite, 1082
2,6-Dimethyl-4-heptanone, physical properties, 900t
Dimethyl isophthalate, physical properties, 585t
Dimethylketene, 898
Dimethyl ketone, 7
Dimethyl maleate, physical properties, 585t
Dimethyl malonate [CAS: 108-59-8], 963
Dimethyl *p*-methoxybenzylidene malonate, 1641
Dimethyl oxalate, physical properties, 585t
2,4-Dimethyl-3-pentanone, physical properties, 900t
4,4-Dimethyl-1-pentene, melting range, 1546t
Dimethyl peroxide, physical properties, 1232t
Dimethyl phthalate
  dye carrier, 512t
  physical properties, 585t
2,2-Dimethyl-1-propanol, physical properties, 89t
1,1-Dimethylpropynyl hydroperoxide, physical properties, 1231t
Dimethyl sulfoxide, 1569–1570
Dimethyl terephthalate
  dye carrier, 512t
  physical properties, 585t
1,5-Dimethyl-6,7,8-trioxabicyclo[3.2.1]octane, boiling point, 1235t
3,3-Dimethyl-1,2,4-trioxolane, boiling point, 1235t
3,5-Dimethyl-1,2,4-trioxolane, boiling point, 1235t
Di(2-naphthaleny carbonyl) peroxide, properties, 1237t
Dinicotinoyl peroxide, properties, 1237t
Dinitramine, environmental health advisories, 771t
1,3-Dinitrobenzene, 1082
  physical properties, 1081t
Di(4-nitrobenzoyl) peroxide, properties, 1237t
2,4-Dinitrotoluene, physical properties, 1081t
Dinonanoyl peroxide, properties, 1237t
Dinoseb, environmental health advisories, 771t
Dioctadecanoyl peroxide, properties, 1237t
Dioctanoyl peroxide, properties, 1237t
Diode lasers, wavelength range, 910t
Dionin, 1041

Diopside, **496–497**
abrasion pH, 1t

physical properties, 18t, 585t
physical properties of polymers, 18t
Ethyl alcohol
combustion constants, 422t
density, 474t
heating value, 686t
specific heat at constant pressure, 757t
Ethyl alcohol [CAS: 64-17-5], **588**
Ethyl amyl ketone, physical properties, 900t
Ethylbenzene, 1765
manufacture, 1555
physical properties, 1766t
Ethylbenzene hydroperoxide, physical properties, 1231t
Ethyl benzoate, physical properties, 585t
2-Ethylbutyl acrylate, physical properties of polymers, 18t
Ethyl butyrate
permeation in selected barrier polymers, 174t
physical properties, 585t
Ethyl carbamate, 1653
Ethyl cellulose, **588-589**
Ethylcellulose, microcapsule material, 997t
Ethyl chloride, physical properties, 366t
Ethyl cyanate, 464
Ethyl cyanoacetate, 964
Ethyl-2-cyano-3,3-diphenyl acrylate, 1641
Ethyl cyanurate, 464
Ethylene
combustion constants, 422t
combustion reactions, 423t
formation from acetylene, 8
heating value, 686t
ignition temperature in air, 425t
measurement by NDIR analysis, 837t
monomer reactivity and suitable initiator for, 838t
plant growth effects, 1314
water-vapor transmission rate, 173t
Ethylenebis, as release agent, 1435t
Ethylenebisdibromonorbornanedicarboximide, flame retardant, 640t
Ethylenebistetra-bromophthalimide, flame retardant, 640t
Ethylene [CAS: 74-85-1], **589-590**
Ethylene cyanohydrin, 465t
Ethylenediamine, physical properties, 483t
Ethylenediamine adduct, commercial polyether polyol, 1654t
Ethylenediamine ditartrate (EDT), for diffracting crystal spectrometer, 1760
Ethylene dichloride, physical properties, 366t
Ethylene glycol [CAS: 107-21-1], 46, **590**, 733
physical properties, 590t
polyol for alkyd synthesis, 53t
Ethylene glycol diacetate, physical properties, 585t
Ethylene monochloride, 8
Ethylene oxide, as propellant, 1447t
Ethylene oxide [CAS: 75-21-8], **590**
definitely established workplace carcinogen, 297t
measurement by NDIR analysis, 837t
Ethylene-vinyl acetate copolymers, **590**
Ethylene-vinyl alcohol copolymer
diffusion and solubility coefficients for oxygen and carbon dioxide, 173t
gas permeability, 172t
permeation of flavor/aroma compounds, 174t
water-vapor transmission rate, 173t
Ethylene-vinyl alcohol (EVOH) copolymers, 1679
Ethyl ether, 100t, 587
physical properties, 587
Ethyl 3-ethoxypropionate, physical properties, 585t
Ethyl formate, physical properties, 585t
Ethyl hexanoate, permeation in selected barrier polymers, 174t
2-Ethylhexyl acetate, physical properties, 585t
2-Ethylhexylacrylate, 17
2-Ethyl hexylacrylate, 20
2-Ethylhexyl acrylate
physical properties, 18t, 585t
physical properties of polymers, 18t
Ethyl hydroperoxide, physical properties, 1231t
Ethylidene diethyl ether, 6
Ethylidene dimethyl ether, 6
Ethyl isobutyrate, physical properties, 585t
Ethyl isocyanate, 464
Ethyl isocyanurate, 464
Ethyl methacrylate, 16-17, 19
physical properties, 988t
Ethyl-2-methyl butyrate, as key odor/tase compound, 649
Ethyl 2-methylbutyrate, permeation in selected barrier polymers, 174t
Ethylnitrate, 1082
Ethylnitrite, 1082
3-Ethyl-3-pentyl hydroperoxide, physical properties, 1231t
Ethyl propyl ketone, physical properties, 900t
Ethyl salicylate, physical properties, 585t
Ethyl stearate, physical properties, 585t
Ethyl urethane, 1653
Ethyl vinyl ether, physical properties, 1690t
Ethyl xanthic acid, 1755
Ethyne, 7
Etidocaine, 100t
Etoposide phosphate, topoisomerase interactive, 357t
Etoposide USP, topoisomerase interactive, 357t
Eucalyptus oil, 647t
Euclase, **590**
Eudiometer, **590**
Eulexin, hormonal therapy, 358t
Europium
abundance, 330t
electronic structure, 336t
interatomic distance, 342t
ionic crystal radius, 341t
nuclides (isotopes and isobars), 331t
principal characteristics, 327t
properties, 1421t, 1422t
Europium [CAS: 7440-53-1], **590-591**
Eutectic, **591**
Eutectoid, **591**
Evaporation, **591-592**
Evaporite, **593**
Even-even nuclei, **593**

nuclides (isotopes and isobars), 331t
percentage in air, 46t
principal characteristics, 327t
standard electrode potential, 31t
in Texas natural gas, 1054t
van der Waals characteristic equation coefficients, 321t
Hydrogen (Fuel), **799–804**
Hydrogen-annealed iron, magnetic properties, 955t
Hydrogenated vegetable oils, microcapsule material, 997t
Hydrogenation, **799**, 1177, 1180
catalyst application, 304t, 305
fats and oils, 1671
Hydrogen bond, 346
Hydrogen [CAS: 1333-74-0], **797–799**
specific heat at constant pressure, 757t
Hydrogen chloride, 797
Hydrogen-ion activity, **804–806**
Hydrogenolysis, 1181
Hydrogen-oxygen cell, 189
Hydrogen peroxide
as parent structure compound, 1090t
as propellant, 1447t
Hydrogen peroxide [CAS: 7722-84-1], **806–807**
Hydrogen scale, **807**
Hydrogen sulfide, 1571
combustion constants, 422t
combustion reactions, 423t
girbotol adsorption, 723
removal from raw water, 1724
in Texas natural gas, 1054t
Hydrogen sulfide [CAS: 7783-06-4], **807**
Hydroisoandrosterone, 98
Hydrolases, 571t
Hydro-lyases, 571t
Hydrolysis, **807**, 1180, 1525
yeast participation, 1769t
Hydrolyzed polyacrylamide, water-soluble polymer, 1737–1738
Hydrometallurgy, 987
Hydromorphone, 92t
Hydronium ion, **807**
Hydrophilic, **807**, 947
Hydrophobic, **807**, 947
Hydroquinones, **807–808**
Hydrotreater, 1255
Hydrotreating, **808**
catalyst application, 304t, 305
Hydrous calcium silicate, insulation material, 856t
Hydroxide minerals, 1011
17-ß-Hydroxy-4-androsten-3-one, where produced, structure, and principal functions, 789t
m-Hydroxybenzoic acid, 1455
p-Hydroxybenzoic acid, 1455
Hydroxycarboxylic acids, **808–809**
17-Hydroxycorticosterone, where produced, structure, and principal functions, 786t
1-Hydroxycyclohexyl 1-hydroperoxycyclohexyl peroxide, 1234t
Hydroxy dicarboxylic acids, **810–811**
3-Hydroxy-1,1-dimethylbutyl hydroperoxide, physical properties, 1231t
3-Hydroxy-1,1-dimethyl-butyl peroxyneodecanoate, properties, 1239t
1-Hydroxyethyl ethyl peroxide, boiling point, 1234t
1-Hydroxyethyl hydroperoxide, 1233t
2-Hydroxyethyl methacrylate, physical properties, 988t
1-Hydroxyethyl methyl peroxide, boiling point, 1234t
Hydroxylamine [CAS: 7803-49-8], **809–810**
Hydroxylases, 571t
Hydroxyl group, analysis, 97
Hydroxyl group alcohols, 46
Hydroxyl radical, and acid-base chemistry, 13
1-Hydroxymethyl-5,5-dimethylhydantoin, 794
Hydroxymethyl hydroperoxide, melting point, 1233t
Hydroxymethyl methyl peroxide, boiling point, 1234t
4-Hydroxy-4-methyl-2 pentanone, physical properties, 900t
2-(2′-Hydroxy-5′-Methylphenyl) benzotriazole, 1641
Hydroxymethyltransferases, 571t
1-Hydroxynonyl hydroperoxide, 1233t
2-Hydroxy-4-octoxybenzophenone, 1641
1-Hydroxyoctyl hydroperoxide, 1233t
1-Hydroxypentyl hydroperoxide, 1233t
Hydroxyproline
first isolation and isoelectric point, 78t
manufacture, 76t
production, 80
structural classification, 79t
2-Hydroxypropyl methacrylate, physical properties, 988t
Hydroxyurea USP, antimetabolite, 355t
Hygrine, 49t
Hygrometry and psychometry, **811–814**
Hygroscopic, **814**
Hyperammonemia, genetic influence, 716
Hyperconjugation, **814**
Hypereutectic alloy, **814**
Hyperfine structure, **814**
Hyperglycemic-glycogenolytic factor, where produced, structure, and principal functions, 787t
Hyperlipoproteinemias, genetic influence, 716
Hyperons, **814**
Hyperprolinemia, genetic influence, 716
Hypersorption, **814**
Hypersthene, **814–815**
Hypobaric (controlled-atmosphere) systems, **815**
Hypochlorination, 1180
Hypochlorites, **815–816**
Hypoeutectic alloy, **816**
Hypofluorite, **816**
Hypoiodites, 816
Hypoiodous acid and hypoiodites, **816**
Hyponitrites, 816
Hyponitrous acid and hyponitrites, **816**
α-Hypophamine, where produced, structure, and principal functions, 788t
Hypophosphates, 816
Hypophosphites, 816
Hypophosphoric acid, 1279
Hypophosphoric acid and hypophosphates, **816**
Hypophosphorous acid, 1279
Hypophosphorous acid and hypophosphites, **816**
Hypophyseal growth hormone, where produced, structure, and principal functions, 789t
Hyposulfites, 816
Hyposulfurous acid and hyposulfites, **816**
Hypothesis, **816**
Hysteresis, **816–817**

Lactogenic hormone, where produced, structure, and principal functions, 788t
Lactone, **908**
ß-Lactones, monomer reactivity and suitable initiator for, 838t
Lactose, 1000
  purification, 863t
Lactose [CAS: 63-42-3], **908**
Ladder polymer, **908**
Lakes, acidification, 9
Lambda particle, **908**
Lambert (L), 1644t
Lamb waves, 1637
Laminar flow, **908**
Laminate, **908**
Lampblack, **908**
Lana, 623t
Landerite, 1755
Land-farming, 205t
Land reclamation, 1440
Land treatment, 205t
Langmuir, Irving (1881–1957), **908–909**
Langmuir adsorption isotherm, 36–37
Langmuir-Blodgett films, 1017–1026
Langmuir-Blodgett film sensors, 1024–1026
Lanolin, 1747
  as release agent, 1435t
Lanthanide contraction, **909**
Lanthanides, principal characteristics of elements, 327–328t
Lanthanide series, **909**
Lanthanum
  abundance, 330t, 1132t
  covalent radius, 344t
  electronic structure, 336t
  interatomic distance, 342t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  principal characteristics, 327t
  properties, 1421t, 1422t
Lanthanum [CAS: 7439-91-0], **909**
Large scale integration, 1017
Laser chemistry, 1285–1286
Laser femtochemistry, 1286
Laser glasses, 725
Lasers, **909–919**
  optical fiber applications, 1156–1157
Latent heat, **920**
Laterite, **920**
Latex, **920**
Latex foam, production methods for cellular, 664t
Latex foam rubber, physical properties of flexible foamed plastics, 665t
Latex technology, **920–921**
Lattice compounds, **921**
Lattice energy of crystal, **921**
Lattice water, 794
Laue pattern, 1758
Lauric acid
  fatty acid in vegetable oil, 1671t
  in major vegetable oils, 1672–1673t
Lauric acid [CAS: 143-07-7], **921**
Laurolactam, monomer for nylon resins, 1333t
Lauryl methacrylate, physical properties, 988t
Lava, **921**
Lavender oil, 647t
Laviosier, Antoine Laurent (1743–1794), **921–922**
Lawrence, Ernest O. (1901–1958), **921**
Lawrencium, 23t
  binary compound properties, 25–26t
  electronic structure, 337t
  oxidation states, 24t
  principal characteristics, 327t
Lawrencium [CAS: 22537-19-5], **921**
Lawsonite, **921**
Lazulite, **921–922**
Lazurite, **922**
Leaching, 987
Lead
  abundance, 330t, 1132t
  constituent of human plasma or serum, 244t
  corrosion resistant alloys, 446t
  density, 474t
  electronic structure, 337t
  EPA pretreatment standard for aqueous discharge, 985t
  in hazardous waste, 1711t
  interatomic distance, 342t
  ionic crystal radius, 341t
  major sources of industrial minerals, 1011t
  nuclides (isotopes and isobars), 331t
  principal characteristics, 327t
  residence time in sea water, 1133t
  specific heat at constant pressure, 757t
  standard electrode potential, 31t
  water quality indicator, 1726
Lead acetate, 6
Lead-acid batteries, **181–182**
Lead base babbits, 923t
Lead [CAS: 7439-92-1], **922–925**
Lead diecasting alloys, antimony content, 139t
Leaded brass, 440t
Lead glasses, 725
Leather beating enzymes, 306
Leavened bread, 1767
Leavening agents, **925–926**
Le Châtelier's Principle, **926**
Lecithin, **926–927**
  constituent of human blood, 242t
Leduc's rulke, **927**
Lee, Yuan T. (1936–), **927**
Lehn, Jean-Marie Pierre (1939–), **927**
Lelanché cell, 179t
  cell reactions, energy content, and manufacturers, 179t
Leloir, Luis F. (1906–1987), **927**
Lemongrass oil, 647t
Lemon oil, 647t
Length of unused bed (LUB), adsorption columns, 37
Lentaron, hormonal therapy, 358t
Lepidocrocite, 871t
Lepidolite, **927**
  mineralogical properties, 993t
Leptons, **927**
Lesch-Nyhan syndrome, genetic influence, 716
Leucine
  first isolation and isoelectric point, 77t
  manufacture, 76t
  production, 80
  in selected foods, 75t
  structural classification, 79t
Leucite, **927–928**
  abrasion pH, 1t
Leuprolide acetate USP, hormonal therapy, 358t
Leupron, hormonal therapy, 358t
Levarterenol, where produced, structure, and principal functions, 788t
Levarternol, 35–36
Levene-Hudson phenylhydrazide rule, **928**
Levorenine, where produced, structure, and principal functions, 786t
Levorotatory, 78, 1543
Levorotatory compounds, **928**
Levorphanol, 92t, 93t, 1041
Lewis, Gilbert N. (1875–1946), **928**
Lewis, Warren P. (1882–1974), **928**
Lewis acid, **928**
Lewis base, **928**
Lewis electron theory, **928**
Lewis salt, 13
Leyden temperature scale, **928**
Libby, Willard P. (1908–1980), **928**
Lidocaine, 100t
Liebig, Justus Von (1803–1873), **928**
Life, origin (Biogenesis), **928**
Ligand, **928–929**, 1542–1543
Ligases, 571t
Light distillate, 1255
Light-emitting diode, optical fiber applications, 1157
Light glass, 1163t
Light-sensitive materials, 1485
Light stabilizer, 1641
Light straight-run, 1255
Light-water reactor (LWR), 1647
Lignaloe, 647t
Lignin, **929**, 1751
Lignite A, characteristics, 390t
Lignite and brown coal, **929–930**
Lignite B, characteristics, 390t
Lime, **930–931**
Lime oil, 647t
Limestone, **930–931**
Limestone [CAS: 1317-65-3], 930–931
D-Limonene, permeation in selected barrier polymers, 174t
Limonite, 871t, **931**
Lincomycin, year of discovery/market introduction, 106t
Lincosaminide antibiotics, **119–120**
Lindane insecticide, in hazardous waste, 1711t
Linear accelerator, 1215
Linear alkane, 1169t
Linear low density polyethylene, 1140t, 1143–1146
Linen, fiber-dye property requirements, 521t
Linnaeite, cobalt source, 410t
Linoleic acid, **931**
Linolenic acid, **931**
  fatty acid in vegetable oil, 1671t

Linotype, 923t
Linseed oil, 1671
  fatty acid composition, 507t
Linuron, environmental health advisories, 771t
Lipase
  metal chelate enzyme, 323t
  target of medical diagnostic test, 975t
  therapeutic enzyme, 574t
Lipids, **931**
  constituent of human blood, 242t
Lipmann, Fritz (1899–1986), **932**
Lipowitz' alloy, bismuth in, 238t
Lippmann hologram, 781
Lipscomb, William N. (1919–), **932**
Liquation, **932**
Liquefied petroleum gas LPG, 1255
Liquid, **932**
Liquid carburizing, 763t
Liquid Chromatography, 41
Liquid chromatography, **932–933**
  for ultratrace analysis, 1627t
Liquid chromatography/mass spectrometry, for ultratrace analysis, 1627t
Liquid crystalline materials, **933–935**
Liquid crystal polymers, **935**
Liquid crystals, **935–937**
Liquid cyaniding, 763t
Liquid junction, **937**
Liquid-liquid absorption, 4–5
Liquid-liquid extraction, **594–598**
Liquid-phase adsorption, 40–42
Liquid-solid extraction, **598–599**
Liquid state, **937–941**
Liquidus curve, 57
Liter (l), 1644t
Lithium, 48
  abundance, 330t, 1132t
  covalent radius, 344t
  electronic structure, 336t
  interatomic distance, 342t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  principal characteristics, 327t
  residence time in sea water, 1133t
  standard electrode potential, 31t
Lithium-acid cell, cell reactions, energy content, and manufacturers, 180t
Lithium-aluminum/iron sulfide cell, 182–183
  cell reactions and energy content (in development), 180t
Lithium-carbon cell, cell reactions, energy content, and manufacturers, 180t
Lithium-carbon monofluoride cell, cell reactions, energy content, and manufacturers, 179t
Lithium [CAS: 7439–93–2], **941–943**
Lithium-copper oxide cell, cell reactions, energy content, and manufacturers, 179t
Lithium-drifted Si detectors, 1759
Lithium fluoride, for diffracting crystal spectrometer, 1760
Lithium hydride, physical properties, 795t
Lithium-iodine cell, cell reactions, energy content, and manufacturers, 179t
Lithium-iron sulfide cell, cell reactions, energy content, and manufacturers, 179t
Lithium-manganese dioxide cell
  cell reactions, energy content, and manufacturers, 179t
  rechargeable, 180t
Lithium-molybdenum disulfide cell, cell reactions, energy content, and manufacturers, 180t
Lithium soap greases, 743
Lithium-solid polymer electrolyte cells, 182
Lithium-sulfur dioxide cell, 185
  cell reactions, energy content, and manufacturers, 179t
Lithium-thionyl chloride cell, 185
  cell reactions, energy content, and manufacturers, 179t
Lithium-vanadium pentoxide (Li-V2O$_5$) cell, 183
  cell reactions, energy content, and manufacturers, 180t
Lithium-vanadium triskaidekaoxide (Li-V_6O_{13}) cell, cell reactions and energy content (in development), 180t
Lithography, nanofabrication application, 1047t
Little, Arthur D. (1863–1935), **943**
LL-E19020ß, formula and producing organism, 116t
LL-E19020α, formula and producing organism, 116t
Local anesthetics, 100–101
Local probe-assisted synthesis, nanofabrication application, 1047t
Locust bean gum, 748t
Lometrexol sodium, antimetabolite, 355t
Lomustine USP, DNA alkylating/cross-linking agent, 356t
London flu, 1694
Long- ultraviolet, 1639
Loose abrasives, 2
Loose-fill Insulation, insulation material, 857
Low alloy steels, 775
Low-alloy steels, 57–58, 58
Low brass, 440t
Low carbon steel, magnetic properties, 955t
Low density polyethylene, 1140t, 1140–1142
  diffusion and solubility coefficients for oxygen and carbon dioxide, 173t
  gas permeability, 172t
  permeation of flavor/aroma compounds, 174t
  water-vapor transmission rate, 173t
Low-density polyethylene (LDPE), in municipal waste, 1714t
Low-quartz, 1397
Lowry-Bronsted acid-base theory, 12
Low volatile bituminous, characteristics, 390t
LSD-25, 566, 754
L shell, 335, 335t
  electronic structure of the elements, 336–337t
Lubricant, **943**
Lubricating agents, **943–946**
Lucovorin, antimetabolite, 355t
Lumen (lm), 1644t
Lumen per square foot (lm/ft2), 1644t
Lumen per square meter (lm/m2), 1644t
Lumen per watt (lm/W), 1644t
Luminescence, **946–947**
Lunar rocks, 1011l
Lupanine, 49t
Lupine alkaloids, 49t
Lustran-35, 21t
Luteinizing hormone (LH), where produced, structure, and principal functions, 787t
Luteoantine, where produced, structure, and principal functions, 787t
Luteosterone, where produced, structure, and principal functions, 788t
Luteotropin, where produced, structure, and principal functions, 787t
Lutetium
  abundance, 330t
  electronic structure, 337t
  interatomic distance, 342t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  principal characteristics, 327t
  properties, 1421t, 1422t
Lutetium [CAS: 7439–94–3], **947**
Lux (lx), 1644t
LY146032, activity and producing organism, 128t
Lyases, 571t
Lycorine, 49t
Lycra, 624t
Lyme disease vaccine, 1660
Lymphocytes, 242t, 243
Lyocell fiber, generic designation and definition, 622t
Lyophilic, **947**
Lyophobic, **947**
Lyotropic series, **389**
Lysergic acid diethylamide (LSD), 566, 754
Lysine
  first isolation and isoelectric point, 78t
  manufacture, 76t
  in selected foods, 75t
  structural classification, 79t
  synthesis from products of carbohydrate metabolism, 282t
Lysodren, chemotherapeutic, 359t
Lysosomal storage abnormalities, genetic influence, 716

Nitrile, 1169t
Nitrile barrier polymers, gas permeability, 172t
Nitrile barrier resins, water-vapor transmission rate, 173t
Nitriles, 74, **1078–1081**
Nitrites, 1082
Nitroalkenes, monomer reactivity and suitable initiator for, 838t
1,3-Nitroaniline, physical properties, 1081t
1-Nitroanthraquinone, physical properties, 1081t
4-Nitrobenzaldehyde, physical properties, 1081t
Nitrobenzene, 1082
physical properties, 1081t
4-Nitrobenzoic acid, physical properties, 1081t
4-Nitrobenzyl alcohol, physical properties, 1081t
Nitrobromoform, physical properties, 1081t
Nitrocellulose-based lacquers, alkyd resins with, 54
Nitrochloroform, physical properties, 1081t
Nitrochlorotoluene, physical properties, 366t
Nitro compound, 1169t
Nitro compounds, **1081–1082**
Nitrodimethylmethane, 1082
Nitroethane, 1082
Nitroethyl alcohol, physical properties, 1081t
Nitrofurane, physical properties, 1081t
Nitrogen
abundance, 330t, 1132t
amount in pure irons, 877t
combustion constants, 422t
constituent of human blood, 242t
covalent radius, 344t
electronic structure, 336t
gas separation, 39t
ionic crystal radius, 341t
mass peaks and relative intensities, 973t
nuclides (isotopes and isobars), 331t
percentage in air, 46t, 424t
permeability in barrier polymers, 172t
plant micronutrient, 613t
principal characteristics, 327t
removal from raw water, 1724
in Texas natural gas, 1054t
van der Waals characteristic equation coefficients, 321t
Nitrogen [CAS: 7727-37-9], **1082–1086**
Nitrogen fixation, 1085–1086
Nitrogen group, **1086–1087**
Nitrogen oxides (NO_x)
in acid rain, 9–12
air pollution, 1327–1328
gas separation, 39t
Nitrogen tetroxide, as propellant, 1447t
Nitroglycerine, 732
Nitro group, analysis, 97
Nitroguanidine, physical properties, 1081t
2-Nitronaphthalene, physical properties, 1081t
3-Nitrophenol, physical properties, 1081t
2-Nitropropane, 1082
physical properties, 1081t
Nitrosamine, 1082
Nitrosobenzene, physical properties, 1082t
Nitroso compound, 1169t
Nitroso compounds, **1081–1082**
2-Nitrosonaphthol-1, physical properties, 1082t
4-Nitrosonaphthol-1, physical properties, 1082t
1-Nitrosonaphthylamine-2, physical properties, 1082t
4-Nitrosophenol, physical properties, 1082t
4-Nitrosophenylaniline, physical properties, 1082t
Nitrosotrimethylmethane, 1082
Nitrostilbene, organic superlattice, 1023
2-Nitrotoluene, physical properties, 1081t
Nitrotrimethylmethane, 1082
Nitrourea, physical properties, 1081t
Nitrous oxide, 100t
as greenhouse gas, 743–744
measurement by NDIR analysis, 837t
percentage in air, 46t
N-Nitrosomethylaniline, physical properties, 1082t
Nobel, Alfred B. (1833–1896), **1087**
Nobelium, 23t
binary compound properties, 25–26t
electronic structure, 337t
interatomic distance, 342t
ionic crystal radius, 341t
oxidation states, 24t
principal characteristics, 327t
Nobelium [CAS: 10028-14-5], **1087**
Nobel Prizes, **1087–1088**
Noble gases, 706
Nolvadex, hormonal therapy, 358t
Nomenclature, **1088–1091**
Nomex, 622t
Nonadecanedioic acid, physical properties, 490t
1-Nonadecene, physical properties, 1150t
trans-2-*cis*-6-Nonadienal, as key odor/tase compound, 649
Nonagglomerating coals, 390t
Nonanedioic acid, physical properties, 490t
Nondestructive testing, **1092–1094**
1-Nonene, physical properties, 1150t
Nonessential amino acids, 75, 76t
Nonheterocyclic nitrogen compounds, 1175
Nonheterocyclic sulfur compounds, 1175–1176
Nonionic surfactants, 1585–1586
Nonpolar compound, 428–429
Nonpolar solvent, 1524
Nonsteroidal antiinflammatory drugs (NSAIDs), 92
chiral, 1268
Nonstoichiometric compound, 428
Nootkatone, as key odor/tase compound, 649
Noradrenaline, 35–36
where produced, structure, and principal functions, 788t
Norepinephrine, 35–36
where produced, structure, and principal functions, 787t
Norite, 701
Normal concentration, **1094**
Norrish, Ronald G. W. (1897–1978), **1094**
Northrup, John H. (1891–1987), **1095**
Noscapine, 91
Novantrone, DNA interactive agent, 357t
Novobiocin, year of discovery/market introduction, 106t
Novolacs, 1274–1275
Noxious gas, **1095**
N shell, 335, 335t
electronic structure of the elements, 336–337t
Nubain, 93t
Nucleaic acids, **1125–1126**
Nuclear chemistry, **1095**
Nuclear fission, **1095–1096,** 1101–1102
Nuclear force, 1210–1211
Nuclear forces, **1096–1097**
Nuclear fuels, 1101–1102
Nuclear fusion, **700, 1097–1098**
Nuclear fusion technology, 694–699
Nuclear isomer, 888
Nuclear magnetic moment, **1098**
Nuclear magnetic resonance (NMR), **1098–1099**
Nuclear potential, **1101**
Nuclear power technology, **1101–1123**
Nuclear selection rules, **1464**
Nuclear spin, **1124**
Nuclear structure, **1124**
Nuclear transmutation, **1124–1125**
Nucleic acids, 12, **1127**
Nucleocapsid, 1693
Nucleonics, **1127**
Nucleons, **1127**
Nucleophile, **1127**
Nucleophiles, activation, 29
Nucleophilic reaction, **1127**
Nucleoproteins, **1127**
Nucleoside, **1127**
Nucleoside antibiotics, **123–124**
Nucleosynthesis, 329
Nucleotide antibiotics, **123–124**
Nucleotide phosphorus, constituent of human blood, 242t
Nucleotides, constituent of human blood, 242t
Nucleotidyltransferases, 571t
Nucleus, **1127**
Nuclides, 330–332, 331t
Nutmeg oil, 647t
Nylon
dielectric permittivity, 852t
dyeing, 523
fiber-dye property requirements, 521t
physical properties of structural foams, 665t
Nylon-6, 623t, 1127
gas permeability, 172t
water-vapor transmission rate, 173t
Nylon-6, 6, 34, 622–623t, 1127
water-vapor transmission rate, 173t
Nylon-6, 10, 1127
Nylon-11, 1127
water-vapor transmission rate, 173t
Nylon-12, 1127
water-vapor transmission rate, 173t
Nylon blends, dyeing, 525
Nylon [CAS: 63428-83-1], **1127–1128**
Nylon fiber
generic designation and definition, 622–623t
physical properties, 1139t
worldwide capacity, 628t
Nylon-6,6 fiber, physical properties of staple, 626t
Nylon-MXD6, gas permeability, 172t
Nylon resin, 1128
Nylon resins, **1332–1334**
Nystatin, year of discovery/market introduction, 106t

Peppermint oil, 647t
Peptide antibiotics, **127**
Peptide hydrolases, 571t
Peptide synthetases, 571t
Peptide vaccines, 1661
Peptidomimetics, chiral, 1269
Peptidyl-amino acid hydrolases, 571t
Peptidyl-peptide hydrolases, 571t
Peptization, **1221**

Peptone. **1221**
Perchlorates. **1221–1223**
Perchloric acid. **1221–1223**
Perfect gas. **1223**
Perfluorocarbons (PFCs). as greenhouse gas. 744
Perfluoro-di-*tert*-butyl peroxide. physical properties. 1232t
Perfluoro dimethyl peroxide. physical properties. 1232t
Perfluorolauric acid. as release agent. 1435t
Perfume. **1223**
Periclase. hardness. 755t
Peridotite. **1223**
Perilla oil. fatty acid composition. 507t
Periodic law. **1224**
Periodic table. **1224–1225**
Peritectic temperature. **1226**
Perkin. Sir William Henry (1838–1907). **1226**
Perlite. **1226**
  insulation material. 856t. 857
Permafil. **1226**
Permanent-press resin. **1226**
Permanent set. **1472**
Permeation. **1226**
Permenorm. **1226**
Permutation. **1226**
Permutation group. **1226**
Perovskite. **1226**
  crystal structure. 455
Peroxidase
  metal chelate enzyme. 323t
  properties as diagnostic enzyme. 976t
Peroxide. 1174
Peroxides and peroxide compounds (Inorganic). **1226–1229**
Peroxides and peroxide compounds (Organic). **1229–1240**
Peroxyacetic acid. 1236t
Peroxybenzoic acid. 1236t
Peroxybutyric acid. 1236t
Peroxycinnamic acid. 1236t
Peroxydecanoic acid. 1236t
Peroxydodecanoic acid. 1236t
Peroxyformic acid. 1236t
Peroxy group. analysis. 97
Peroxyhexadecanoic acid. 1236t
Peroxyhexanoic acid. 1236t
Peroxynonanoic acid. 1236t
Peroxyoctadecanoic acid. 1236t
Peroxyoctanoic acid. 1236t
Peroxypropionic acid. 1236t
Peroxytetradecanoic acid. 1236t
Peroxyxanthates. 1755
Perrhenic acid. **1240**
Perrin rule. **1240**
Perthite. **1240**
Perturbation. **1240**
Perutz. Max F. (1914–2002). **1240**
Pesticides. **848–851**
  pyridine derivatives. 1386
Petalite. **1240**
Petrochemicals. **1240–1242**
Petrolatum. **1242**. 1748
Petroleum. **1242–1254**
  pollution in oceans. 1731–1732
Petroleum ceresins. 1748
Petroleum exploration. 1245–1247
Petroleum exploratory drilling. 1247–1248
Petroleum refining. **1255–1260**
Petroleum reserves. 1254
Petroleum terminology. 1257–1259
Petroleum waxes. 1748
Petroleum wells. 1245–1253
Pettigrain oil. 647t
Pewter. antimony content. 139t
pH (Abrasion). **1–2. 1261**
Pharmaceuticals. **1262–1265**
  chiral. **1265–1269**
  pyridine derivatives. 1386–1388
Pharmacodynamics. **1269–1273**
Pharmacokinetics. 1263
Phase diagram (Metallurgy). **1273**
Phase rule. **1273**
Phenacite. **1273**
Phenanthrene. biodegradable. 207t
Phenazocine. 92t. 93t. 1041
Phenelfamycin A. formula and producing organism. 116t
Phenelfamycin B. formula and producing organism. 116t
Phenelfamycin C. formula and producing organism. 116t
Phenelfamycin D. formula and producing organism. 116t
Phenelfamycin E. formula and producing organism. 116t
Phenelfamycin F. formula and producing organism. 116t
ß-Phenethyl alcohol. **193**
Phenobarbitone. target of medical diagnostic test. 975t
Phenoclast. **1273**
Phenocryst. **1273**
Phenol. **1273–1274**
  as parent structure compound. 1090t
Phenolase. metal chelate enzyme. 323t
Phenolate process. **1274**
Phenol coefficient. **1274**
Phenol-furfural resin. **1274**
Phenolic adhesives. load-bearing capabilities. 32t
Phenolic resin. production methods for cellular. 664t
Phenolic resin adduct. commercial polyether polyol. 1654t
Phenolic resins. **1274–1275**
Phenolics. **1275**
  dielectric permittivity. 852t
Phenolphthalein. pH range and color change of indicator. 825t
Phenol Red. pH range and color change of indicator. 825t
Phenolsulfonphthalein. pH range and color change of indicator. 825t
Phenylacetone. physical properties. 900t
Phenylalanine
  first isolation and isoelectric point. 77t
  manufacture. 76t
  in selected foods. 75t
  structural classification. 79t
Phenylalanine hydroxylase. metal chelate enzyme. 323t
Phenylamine. 75. 101
1-Phenyl-2-aminopropane. 88
Phenylephrine hydrochloride. 52
Phenylephrine tyramine. 49t
2-Phenylethanol. 193
Phenyl ethyl ketone. physical properties. 900t
Phenylhydrazine. 794–795
Phenylhydrazones. 795
Phenyl isocyanate. 464
Phenylketonuria. genetic influence. 716
1-Phenyl-2-methylaminopropanol. 51
o-Phenylphenol. dye carrier. 512t
p-Phenylphenol. dye carrier. 512t
1-Phenyl-2-propanone. physical properties. 900t
Phenytoin. target of medical diagnostic test. 975t
pH (Hydrogen Ion Concentration). **1261–1262**
Phillipsite. **1275**
  composition. 1034t
Phlogopite. **1275–1276**
  mineralogical properties. 993t
Phloridzin. 734t
Phonons. **1276**
Phon (phon). 1644t
Phormium. 632t
Phorone. 7
Phosgenite. **1276**
Phosphate. target of medical diagnostic test. 975t
Phosphate minerals. 1012
Phosphate plasticizers. 1316
Phosphate rock. **1276**
Phosphates. in 24 hour urine sample. 1657t
Phosphazene. **1276**
Phosphine. 1279
6-Phosphogluconic acid. 283
6-Phosphogluconic acid dehydrogenase. 283
3-Phosphoglycerate kinase. metal chelate enzyme. 323t
Phospholipids. **1276**
Phosphonitrile. **1276**
Phosphor bronze. 440t
Phosphorescence. **1277**
Phosphoric acid. acidulant. 14
Phosphoric acid [CAS: 7664-38-2]. **1276–1277**
Phosphoric diester hydrolases. 571t
Phosphoric monoester hydrolases. 571t
Phosphorus. abundance. 1132t
Phosphorous acid. 1279
Phosphors. **1277**
Phosphorus
  abundance. 5t. 330t
  amount in pure irons. 877t
  constituent of human plasma or serum. 244t
  covalent radius. 344t
  electronic structure. 336t
  essential mineral nutrient. 1002. 1002t
  interatomic distance. 342t
  ionic crystal radius. 341t
  nuclides (isotopes and isobars). 331t
  plant micronutrient. 613t
  principal characteristics. 327t
Phosphorus [CAS: 7723-14-0]. **1277–1281**
Phosphorus (In Biological Systems). **1281–1283**
Phosphorylation (Oxidative). **1283**
Phosphorylation (Photosynthetic). **1283–1284**
Phosphotransferases. 571t
Photochemistry. **1284–1286**
Photoelectric constant. **1287**
Photoelectric effect. **1287–1288**
  gamma rays from. 704
Photoelectron spectroscopy. **553**
Photoemission. **1288**
Photographic chemistry. **1288**
Photographic emulsions. 1290–1291
Photographic grade. **1288**
Photography and imagery. **1288–1294**
Photoionization. **1294**
Photoisomerization. 1178
Photolithography. nanofabrication application. 1047t
Photoluminescence. 946t
Photolysis. **1284–1286**
Photometers. **1294–1295**
Photometric analysis. **1295**
Photomultipliers. **1288**
Photon. **1295–1296**
Photoneutron. **1296**
Photonics. **1295–1296**

  electronic structure, 337t
  interatomic distance, 342t
  ionic crystal radius, 341t
  principal characteristics, 327t
Polonium [CAS: 7440-02-06], **1331**
Polonovski reaction, **1331**
Polyacetylene, **1331–1332**
Polyacrylamide, physical properties, 15t
Polyacrylamides, 15–16
Poly(acrylic acid), water-soluble polymer, 1738
Polyallomer resins, **1332**
Polyamide, microcapsule material, 997t
Polyamide-imide resins, **1334**
Polyamide resins, **1332–1334**
Polyamides
  dyeing, 523
  ultrafiltration media application, 1635
Polyarylates, **1334**
Polybasic acids, 13
Polybasite, **1334**
Polybenzimidazole fiber
  generic designation and definition, 623t
  physical properties, 1139t
Polybenzimidazoles, **1334**
Polybutene, 1150
Poly(*n*-butyl acrylate), physical properties, 18t
Poly(*sec*-butyl acrylate), physical properties, 18t
Poly(*tert*-butyl acrylate), physical properties, 18t
Polybutylene resins, **1335**
Polybutylene terephthalate polyesters, **1335**
Polycarbonate
  dielectric permittivity, 852t
  outdoor stability, 990t
  physical properties of structural foams, 665t
  water-vapor transmission rate, 173t
Polycarbonates, **1335–1336**
Polychlorinated biphenyls (PCBs), definitely established workplace carcinogen, 297t
Polycondensation polymerization, 1341
Polycyclic alkane, 1169t
Poly(cyclohexyl acrylate), physical properties, 18t
Polycyclo-hexylene-dimethylene terephthalate, **1336–1337**
Polycystic ovary syndrome, 99
Polydextrose, use in food processing, 671t
Poly(dibromostyrene), flame retardant, 640t
Polydimethylsiloxane, **1337**
  as release agent, 1435t
Poly(dodecyl acrylate), physical properties, 18t
Polyelectrolytes, **1337**
Polyene, **1337**
Polyester, physical properties of structural foams, 665t
Polyester-acrylic fiber blends, dyeing, 525
Polyester fiber
  dyeing, 523–524
  fiber-dye property requirements, 521t
  generic designation and definition, 623t
  physical properties, 1139t
  physical properties of staple, 626t
  worldwide capacity, 628t

Polyester fibers, **1337–1338**
Polyester film, **1338**
Polyester-nylon fiber blends, dyeing, 525
Polyester polyols, 1654
Polyester resins, **1338**
Polyether, physical properties of rigid foamed plastics, 664t
Polyether antibiotics, **127–129**
Polyether-etherketone, **1338**
Polyetherimide, **1338**
Polyether polyols, 1654
Poly(2-ethoxyethyl acrylate), physical properties, 18t
Poly(ethyl acrylate), physical properties, 18t
Poly(2-ethylbutyl acrylate), physical properties, 18t
Polyethylene, 1139–1140, **1338–1339**
  dielectric permittivity, 852t
  physical properties of flexible foamed plastics, 665t
  production methods for cellular, 664t
Poly(ethylene glycol), commercial polyether polyol, 1654t
Polyethylene terephthalate
  dielectric permittivity, 852t
  in municipal waste, 1714t
Poly(ethylene terephthalate)
  diffusion and solubility coefficients for oxygen and carbon dioxide, 173t
  gas permeability, 172t
  water-vapor transmission rate, 173t
Polyethylene wax, as release agent, 1435t
Poly(2-ethylhexyl acrylate), physical properties, 18t
Poly(2-ethyl-2-oxazoline), water-soluble polymer, 1738
Poly(fluoroethers), as release agent, 1435t
Polyhalite, **1338–1339**
Poly(heptyl acrylate), physical properties, 18t
Poly(2-heptyl acrylate), physical properties, 18t
Poly(hexadecyl acrylate), physical properties, 18t
Poly(hexyl acrylate), physical properties, 18t
Polyimide adhesives, load-bearing capabilities, 32t
Polyimides, **1339–1341**
Poly(isobornyl acrylate), physical properties, 18t
Poly(isobutyl acrylate), physical properties, 18t
cis-Polyisoprene, 1449
Poly(isopropyl acrylate), physical properties, 18t
Polymeric isocyanates, 1654
Polymerization, **1341–1342**
  catalyst application, 304t
Polymerization (Emulsion), **1342**
Polymerization (Oxidative-coupling), **1342–1343**
Polymerization (Radical), **1343–1344**
Polymers, 1169t, **1345–1346**
Polymers (Electroconductive), **1346–1347**
Polymers (Inorganic), **1347–1348**
Polymers (Organic), **1348–1350**
Polymers (Water-soluble), **1350, 1736–1738**
Poly(methacrylic acid), water-soluble polymer, 1738
Polymethine dyes, **1350–1352**
Poly(methyl acrylate), physical properties, 18t
Polymethylbenzenes, **1352–1353**
Poly(methyl methacrylate), outdoor stability, 990t
Polymethyl(nonafluorohexyl)-siloxane, as release agent, 1435t
Poly(4-methyl-1-pentene), 1150
Poly(methyl vinyl ether), 1689
Polymorphism, **1353**
Polymorphonuclear leukocytes, 242t
Polymycin A, activity and producing organism, 128t
Polymyxin, year of discovery/market introduction, 106t
Polymyxin E, activity and producing organism, 128t
Polymyxins, activity and producing organism, 128t
Polynuclear aromatic hydrocarbons (PAHs), 298
  definitely established workplace carcinogen, 297t
Polynucleotide phosphorylase, metal chelate enzyme, 323t
Polyol, **1353**
Polyolefin, **1353**
Polyolefin fiber, physical properties of staple, 626t
Polyorganosilicate graft polymer, **1353**
Polyoxalkylene, as release agent, 1435t
Polyoxyethylene, 1737
Poly(pentabromo-benzylacrylate), flame retardant, 640t
Polypeptide, **1353**
Polypeptide hormonal dysfunctions, genetic influence, 716
Polyphenol oxidase, source and function, 986t
Poly(propyl acrylate), physical properties, 18t
Polypropylene, 1146–1147
  dielectric permittivity, 852t
  diffusion and solubility coefficients for oxygen and carbon dioxide, 173t
  fiber-dye property requirements, 521t
  gas permeability, 172t
  in municipal waste, 1714t
  permeation of flavor/aroma compounds, 174t
  physical properties of flexible foamed plastics, 665t
  physical properties of structural foams, 665t
  as release agent, 1435t
  water-vapor transmission rate, 173t
Polypropylene [CAS: 9003-07-0], **1354**
Polypropylene fiber, worldwide capacity, 628t
Poly(propylene glycol), commercial polyether polyol, 1654t
Polysaccharides, 279t
  constituent of human blood, 242t
Polystyrene, 1556–1557
  dielectric permittivity, 852t
  gas permeability, 172t
  insulation material, 856t
  in municipal waste, 1714t
  physical properties of rigid foamed plastics, 664t
  production methods for cellular, 664t
  water-vapor transmission rate, 173t
Polystyrene [CAS: 9003-53-6], **1354–1355**
Polysulfide sealants, 1463
Polysulfone, **1355**, 1567–1568
Polysulfones, ultrafiltration media application, 1635
Polyterpenoids, 1601
Polytetrafluoroethylene, 662
  dielectric permittivity, 852t
  production methods for cellular, 664t
  as release agent, 1435t
Poly(tetramethylene glycol), commercial polyether polyol, 1654t
Polytropic processes, **1355–1356**
Polyunsaturated fats, 1671
Polyurea, microcapsule material, 997t
Polyurethane, 1653–1656
  insulation material, 856t
  physical properties of flexible foamed plastics, 665t
  physical properties of rigid foamed plastics, 664t
  physical properties of structural foams, 665t
  production methods for cellular, 664t
Polyurethane adhesives, load-bearing capabilities, 32t
Polyurethane-modified isocyanurate (PUIR) foams, 1653, 1655
  typical formulation, 1655t
Polyurethanes [CAS: 9009-54-5], **1356**
Poly(vinyl acetate)
  dielectric permittivity, 852t
  physical properties, 1677t
Poly(vinyl alcohol), 1678–1679
  physical properties, 1679t
  as release agent, 1435t
  water-soluble polymer, 1737
Polyvinyl alkyl ethers, **1356**
Poly(vinyl butyral), 1675, 1676
Poly(vinyl chloride), 1682, 1685–1688

  diffusion and solubility coefficients for oxygen and carbon dioxide, 173t
  gas permeability, 172t
  insulation material, 856t
  physical properties, 1686t
  physical properties of rigid foamed plastics, 664t
  production methods for cellular, 664t
  water-vapor transmission rate, 173t
Poly(vinyl chloride) [CAS: 9002-86-2], **1356–1357**
Poly(vinyl fluoride), dielectric permittivity, 852t
Poly(vinyl formal), 1675, 1676
Poly(vinylidene chloride), 1691–1693
  physical properties, 1692t
Poly(vinylidene chloride) [CAS: 9002-86-2], **1357–1358**
Poly(vinylidene fluoride), **1358**
  ultrafiltration media application, 1635
Polyvinylpyrrolidinone, 1680
Poly(*N*-vinyl-2-pyrrolidinone), 1680, 1681–1682
Poly(vinylpyrrolidinone-*co*-vinyl acetate), 1682
Poly(vinyl pyrrolidone), water-soluble polymer, 1738
Polywater, 1722
Poly(*p*-xylylene) (PPX), 1763 1765
Pomeranz-Fritsch reaction, **1358**
Pompe's disease, genetic influence, 716
Population genetics, 711–712
Population inversion, 1158
Porcelain, **1358**
Porcelain, Zircon, **1358**
Porcelain enamel, **1358**
Porcelain enamels, **560–561**
Pore, **1358**
Poromeric, **1358**
Porphyrias, genetic influence, 716
Porphyrin, **1358–1359**
Porphyrins, synthesis from products of carbohydrate metabolism, 282t
Porphyry, **1359**
Porter, George (1920–2002), **1359**
Portland cement, 750
Positive-negative acid-base theory, 12
Positron, **1359**
Positron emission tomography (PET), 1762
Positronium, **1359**
Potassium, 48
  abundance, 5t, 330t, 1132t
  constituent of human plasma or serum, 244t
  covalent radius, 344t
  electronic structure, 336t
  essential mineral nutrient, 1002t, 1002–1003
  in 24 hour urine sample, 1657t
  interatomic distance, 342t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  plant micronutrient, 613t
  principal characteristics, 327t
  residence time in sea water, 1133t
  standard electrode potential, 31t
  water quality indicator, 1726
Potassium (In Biological Systems), **1362–1364**
Potassium acid tartrate
  acidulant, 14
  properties of leavening acid, 925t

Potassium alginate, 748t
Potassium alum, 61
Potassium bicarbonate, alkalizer, 14
Potassium bromate, 1361
Potassium *n*-butyl xanthate, 1755t
Potassium carbonate, 1361
  alkalizer, 14
Potassium [CAS: 7440-09-7], **1360–1362**
Potassium chlorate, 1361
Potassium chloride, 1361
Potassium chloroplatinate, 1361
Potassium chromate, 1361
Potassium cyanate, 1361
Potassium cyanide, 1361
Potassium dichromate, 1361
Potassium dihydrogen phosphate, crystal structure, 455
Potassium hydride, physical properties, 795t
Potassium hydrogen oxalate, 1185
Potassium hydroxide, 12, 1361
  alkalizer, 14
Potassium hypophosphite, 1361
Potassium iodate, 1361
Potassium isoamyl xanthate, 1755t
Potassium isobutyl xanthate, 1755t
Potassium isopropyl xanthate, 1755t
Potassium manganate, 1361
Potassium nitrate, 1361
Potassium nitrite, 1361
Potassium oxalate, 1185
Potassium perchlorate, 1361
Potassium periodate, 1361
Potassium permanganate, 1361
Potassium persulfate, 1362
Potassium *n*-propyl xanthate, 1755t
Potassium silicate, 1362
Potassium sulfate, 1362
Potassium sulfide, 1362
Potassium sulfite, 1362
Potassium superoxide, 1580
Potassium thiocarbonate, 1362
Potassium thiocyanate, 1362
Potassium titanate fiber, insulation material, 856t
Potatoes, susceptibility to iron deficiency, 874t
Potentiator, **1364**
Potentiometric titration, **1621–1622**
Pound, Robert (1919–), **1364**
Poundal (pdl), 1644t
Pour point, **1364**
Pour point depressant, **1364**
Powder, **1364**
Powder metallurgy, **1364–1365**
Poxviruses, 1695
ppb (parts per billion), **1366**
ppm (parts per million), **1366**
Prandtl number, **1366**
Praseodymium
  abundance, 330t
  electronic structure, 336t
  interatomic distance, 342t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  principal characteristics, 328t
  properties, 1421t, 1422t
Praseodymium [CAS: 7440-10-0], **1366**
Precipitate, **1366**
Precipitation hardening, **1366–1367**
Precursor, **1367**
Prednisolone, 93
  commercial microbial transformations used to produce, 1550t
Prednylidene, commercial microbial transformations used to produce, 1550t
Preferential, **1367**
Pregel, Fritz (1869–1930), **1367**
Prehnite, **1367**
Preionization, **161**
Prelog, Vladimir (1906–1998), **1367**
Premix molding, **1367**
Prepolymer, **1367**
Preservative, **1367**
Pressure, **1367–1369**
Pressure measurement, 1368
Pressure sensitive adhesives, load-bearing capabilities, 32t
Pressure-sensitive adhesives, 33
Pressure swing adsorption, 38t
Pressure-swing adsorption, 40
Pressurized water nuclear reactor, 1106–1109, 1120
Priestley, Joseph (1733–1804), **1369**
Prigogine, Ilya (1917–2003), **1369**
Prills, **1369**
Prilocaine, 100t
Primary alcohols, 46
Primary amides, 74
Primary amines, 74, 75
Primary amino group, analysis, 97
Primary wastewater treatment, 1724
Prinadol, 93t
Principal quantum number, 1396
Pristinamycin IA, activity and producing organism, 128t
Pristinamycin IIA, activity and producing organism, 128t
Procaine, 100t
Procarbazine hydrochloride USP, DNA interactive agent, 357t
Process-activating proteins, 1374
Process analyzers, 94
Progesterone, where produced, structure, and principal functions, 788t
Progestin, where produced, structure, and principal functions, 788t
Progressive multifocal leukoencephalopathy, 1696
Prolactin LTH, where produced, structure, and principal functions, 788t
Prolan A, where produced, structure, and principal functions, 787t
Prolinase, metal chelate enzyme, 323t
Proline
  first isolation and isoelectric point, 78t
  manufacture, 76t
  structural classification, 79t
Promethium
  electronic structure, 336t
  interatomic distance, 342t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  principal characteristics, 328t
  properties, 1421t, 1422t
Promethium [CAS: 7440-12-2], **1369**
Prometon, environmental health advisories, 771t
Prometryn, environmental health advisories, 771t
Promoter, **1369**
Pronamide, environmental health advisories, 771t
Proof, **1369**
Propachlor, environmental health advisories, 771t
Propaldehyde, 48
Propane
  combustion constants, 422t
  measurement by NDIR analysis, 837t
  in Texas natural gas, 1054t
Propane [CAS: 74-98-6], **1369**
Propanedioic acid, physical properties, 490t
Propanesulfonic acid, physical properties, 1568t
Propanetriol, 732
Propanil, environmental health advisories, 771t
Propanone, 7
2-Propanone, physical properties, 900t
Propazine, environmental health advisories, 771t
2-Propenal, 14–15
2-Propeneamide, 15
Propenoic acid, 17
Propenoic acid nitrile, 20
Propham, environmental health advisories, 771t
Propionic acid, carboxylic acid, 294
Propionylerythromycin mercaptosuccinate, commercial products, 121t
Propiophenone, physical properties, 900t
Proportional counter, 1759, 1760
Proportional detectors, gamma rays, 704
Propoxyphene, 93t
Propyl acetate, physical properties, 585t
Propyl acrylate, physical properties of polymers, 18t
n-Propyl alcohol, heating value, 686t
Propyl butyrate, permeation in selected barrier polymers, 174t
Propylene
  combustion constants, 422t
  melting range, 1546t
Propylene cyanohydrin, 465t
1,2-Propylenediamine, physical properties, 483t
Propylene nitrile, 20
Prostaglandins, **1369–1370**
Protactinium, 23t
  abundance, 330t, 1132t
  binary compound properties, 25–26t
  electronic structure, 337t
  interatomic distance, 342t
  ionic crystal radius, 341t
  oxidation states, 24t
  physical properties, 24t
  principal characteristics, 328t
Protactinium [CAS: 7440-13-13], **1370**
Protease, **1371**
Proteases, 306
Protective coating, **1371**
Protein hydrolysate, **1371**
Protein in cerebrospinal fluid, target of medical diagnostic test, 975t
Proteins, **1371–1377**
  constituent of human blood, 242t
Proteus, amphenicol susceptibility, 115t
Proteus vulgaris, gram-negative, 168t
Prothrombin factor, 1706
Protium, **1378**
Proton, 1210, **1378**
Proton-proton reaction, **1378**
Protopine, 49t
Proustite, **1378**
Providencia, amphenicol susceptibility, 115t
Provirus, 1695
Provitamin, **1378**
Pseudogenes, 715
Pseudohypoparathyroidism, genetic influence, 716
Pseudomonas, amphenicol susceptibility, 115t
Pseudomonas aeruginosa, gram-negative, 168t
Pseudomones aeruginosa, ß-lactamase-producing bacterium, 110t
Pseudomorphs, **1378**
Pseudopelletierine, 49t
Pseudopotential theory, 346–347
Pseudoxanthoma elasticum, genetic influence, 716
P shell, electronic structure of the elements, 336–337t
Psilocin, 754
Psilocybin, 566, 754

Psilomelane, **1378**
Psi particle, **1378**, 1397
Psychrophilic organism, 1768
Ptomaine, **1379**
Pulp (Wood) production and processing, **1379–1382**
Pultrusion, **1382**
Pumice, **1382**
  abrasive properties, 745t
  hardness, 1008t
Pump and treat, 205t
Pumping plants, 1722
PUREX process, 1647
Purines, constituent of human blood, 242t
Purines [CAS: 120-73-0], **1382**
Purinethol, antimetabolite, 355t
PVC resins, 1686–1687
PVP hydrogels, 1680–1681
Pycnometer, **1382**
Pyrargyrite, **1382**
Pyrazoles, **1382–1384**
Pyrazolines, **1382–1384**
Pyrazolones, **1382–1384**
Pyresis, 91
Pyrex, thermal conductivity, 758t
Pyrex (Corning 7740), dielectric permittivity, 852t
Pyridine, as parent structure compound, 1090t
Pyridine and derivatives, **1384–1385**
Pyridine [CAS: 110-86-1], **1384–1385**
Pyridinium tetracyanoquinodimethane molecular system, 1023
Pyridoxine, 1700–1701
Pyridoxol, 1700
ß-Pyridyl-α-*N*-methylpyrrolidine, 51
Pyrite, 871t, 1009t, **1389**
  crystal structure, 455
  hardness, 1008t
Pyrogenetic minerals, **1389**
Pyrolusite, **1389**
Pyrolysis, **1389**
Pyrometer, **1389**
Pyrometric cones, **1389–1390**
Pyromorphite, **1390**
Pyromucic acid, carboxylic acid, 294
Pyronine B (CI 45010), 1756
Pyronine G (CI 45005), 1756
Pyronines, 1756
Pyrope, 705
Pyrophoric material, **1390**
Pyrophosphoric acid, 1279
Pyrophosphotransferases, 571t
Pyrophyllite, **1390**
Pyrotechnics, **1390**
Pyroxene, **1390**
Pyrrhotite, 871t, **1390**
Pyrrole and related compounds, **1390–1391**
Pyrrole [CAS: 109-97-7], **1390–1391**
Pyruvate kinase deficiency, genetic influence, 716
Pyruvic acid, 282
  constituent of human blood, 242t

Q

Qionones, **1401–1403**
Q shell, electronic structure of the elements, 336–337t
Quad, **1393**

Streaming (Molecular), **1553**
Streams, acidification, 9
Streptococcus fecalis, gram-positive, 168t
Streptococcus hemolyticus, gram-positive, 168t
Streptococcus lactis, gram-positive, 168t
Streptococcus pneumonae, amphenicol susceptibility, 115t
Streptococcus salivarius, gram-positive, 168t
Streptococcus viridans, gram-positive, 168t
Streptogramin A, activity and producing organism, 128t
Streptogramin B, activity and producing organism, 128t
Streptokinase, therapeutic enzyme, 574t
Streptomycin, year of discovery/market introduction, 106t
Streptothricin A, activity and producing organism, 128t
Streptovaricins, biological activity, 108t
Streptozocin USP, DNA alkylating/cross-linking agent, 356t
Stress, 538–539
Stromatolite, **1553**
Strontianite, **1553**
Strontium, 49
  abundance, 330t, 1132t
  covalent radius, 344t
  electronic structure, 336t
  interatomic distance, 342t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  principal characteristics, 328t
Strontium [CAS: 7440-24-6], **1553–1554**

Strontium hydride, physical properties, 795t
Strontium superoxide, 1580
Strontrium, residence time in sea water, 1133t
Structural adhesives, 33
  load-bearing capabilities, 32t
Structural genese, 712
Structural isomers, 1542
Structural proteins, 1374
Strychnine, 49t, 52
Styrene, **1554–1556**
  melting range, 1546t
  polymerization with acrylic monomers, 17
Styrene-acrylonitrile (SAN), 21
Styrene-butadiene rubber, **1556–1557**
Styrene-butadiene-rubber, physical properties of flexible foamed plastics, 665t
Styrene-maleic anhydride, **1557**
Styrenes, monomer reactivity and suitable initiator for, 838t
Sub, **1557–1558**
Subacute sclerosing panencephalitis, 1696
Subbituminous A, characteristics, 390t
Subbituminous B, characteristics, 390t
Subbituminous C, characteristics, 390t
Suberic acid, monomer for nylon resins, 1333t
Subgroups, 746
Sublimation, **1557–1558**
Sublimation (Heat of), **1558**
Substitute natural gas (SNG), **1558–1563**
  heating value, 686t
Substitution, 1178
Subtilin, activity and producing organism, 128t
Subtractive color process, **1563**
Succineins, 1756
Succinic acid, 282t
  acidulant, 14
Succinic acid dehydrogenase, 282t
α-Succinic acid thiokinase, 282t
Sucrose, purification, 863t
Sucrose adduct, commercial polyether polyol, 1654t
Sudangrass, susceptibility to iron deficiency, 874t
Sugar, **1563–1565**
Sugar beets, susceptibility to iron deficiency, 874t
Sugarcane wax, 1747
Sugars, industrial chemicals derived from, 229t
Sulfamation, 1567
Sulfamic acid, reagent for sulfonation, 1566t
Sulfanilamide, 1565
Sulfate
  in 24 hour urine sample, 1657t
  water quality indicator, 1726
Sulfate minerals, 1012
Sulfation, 1567
Sulfhydryl group, analysis, 97
Sulfide minerals, 1011
Sulfometuron, environmental health advisories, 771t
Sulfonamide drugs, **1565**
Sulfonamides, 74
Sulfonation, 1180, **1565–1566**
Sulfone polymers, **1567–1568**
Sulfonic acids, **1568–1569**
Sulforhodamine B (Acid Red 52; CI 45100), 1756
Sulfotransferases, 571t
Sulfoxides, **1569–1570**
Sulfur
  abundance, 5t, 330t, 1132t
  amount in pure irons, 877t
  combustion constants, 422t
  combustion reactions, 423t
  constituent of human plasma or serum, 244t
  content of petroleum, 1243
  covalent radius, 344t
  electronic structure, 336t
  essential mineral nutrient, 1002, 1002t
  ignition temperature in air, 425t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  plant micronutrient, 613t
  principal characteristics, 328t
  in representative U.S. crude oils, 1242t
  in representative world crude oils, 1243t
Sulfur (In Biological Systems), **1573–1575**
Sulfuranes, 1571
Sulfur [CAS: 7704-34-9], **1570–1572**
Sulfur dioxide
  in acid rain, 9–12
  air pollution, 1327
  combustion constants, 422t
  gas separation, 39t
  measurement by NDIR analysis, 837t
  reagent for sulfonation, 1566t
Sulfur dyes, 512t, 514
  applications, 519
  dyeing process, 522
Sulfur fiber, generic designation and definition, 624t
Sulfur hexafluoride, as greenhouse gas, 744
Sulfuric acid, 12, 13
  acidulant, 14
  conductivity-concentration curve, 546
  reagent for sulfonation, 1566t
Sulfuric acid [CAS: 7664-93-9], **1572–1573**
Sulfuric ester hydrolases, 571t
Sulfurous acid [CAS: 7782-99-2], **1575**
Sulfurtransferases, 571t
Sulfur trioxide, reagent for sulfonation, 1566t
Sulfuryl chloride, reagent for sulfonation, 1566t
Sulindac, 93t
Sulofenur, chemotherapeutic, 359t
Sunflower oil, 1671
  fatty acid composition, 507t
Sunn, 632t
Superabrasive wheels, 2
Superacids, 13
Superalloys, 56
  high temperature, 774t
Superconducting Super Collider, 1217

  and conservation laws, **432–434**
Synchrotron, 1215–1216
Synchrotron radiation, 1216–1217
  medical imagery application, 1762
Syndiotactic 1,2-butadiene, melting range, 1546t
Syneresis, **1591**
Synge, Richard L. M. (1914–1994), **1591**
Synmonicin A, producing organism, 118t
Synmonicin B, producing organism, 118t
Synmonicon C (CWI-785), producing organism, 118t
Syntex, 93t
Synthesis (Chemical), **1591–1592**
Synthesis gas, **1592**
  ammonia production from, 83–85
Synthetases, 571t
Synthetic abrasives, 745
Synthetic gemstones, 707
  manufacture, 708
Synthetic latex house paints, 54
Synthetic methyl acetone, 7
Synthetic narcotics, 1041
Synthetic resins, **1438**
Synthetic rubber, **1452**
Synthetic tausonite, 708
Synthetic waxes, 1748–1749
Synthetic zeolites, 1034–1036
  composition, 1034t
  preparation, 1035t

T

Tableting, 44–45
TACE, hormonal therapy, 358t
Tachylite, 1593
Tachylyte, **1593**
Taconite, **1593**
Tacticity, **1593**
Tafel rearrangement, **1593**
Talc
  hardness, 2t, 755t
  as release agent, 1435t
Talc [CAS: 14807-96-6], **1593**
Tallow, higher alcohol manufacture from, 47
Talwin, 93t
Tamm levels, **1593**
Tamoxifen citrate USP, hormonal therapy, 358t
Tannin, **1593**
Tannins, 733, 734t
Tantalite, **1594**
Tantalum
  abundance, 330t
  corrosion resistant alloys, 446t
  covalent radius, 344t
  electronic structure, 337t
  interatomic distance, 342t
  ionic crystal radius, 341t
  major sources of industrial minerals, 1011t
  nuclides (isotopes and isobars), 331t
  physical properties of high temperature, 774t
  principal characteristics, 328t
  properties of refractory, 1075t

Tantalum carbide
hardness, 755t
plasma synthesis, 318t
Tantalum [CAS: 7440-2-5]7, **1594–1595**
Tantalum hydride, physical properties, 796t
Tantalum nitride, plasma synthesis, 318t
Tanzanite, 1779
Tar acid, **1595**
Tarnish, **1595**
Tar sand, 1243
Tar sands, **1595–1596**
Tartaric acid
acidulant, 14
carboxylic acid, 294
Tartaric acid [CAS: 87-69-4], **1596**
Tarui's disease, genetic influence, 716
Taube, Henry (1915–), **1596**
Tau particle, **1596**
Tauromustine, DNA alkylating/cross-linking agent, 356t
Taxol, tubulin interactive, 358t
Taxotere, tubulin interactive, 358t
Tay-Sachs, genetic influence, 716
TCA, environmental health advisories, 771t
TCA cycle, **1596–1597**
Tebuthiuron, environmental health advisories, 771t
Technetium
covalent radius, 344t
electronic structure, 336t
interatomic distance, 342t
ionic crystal radius, 341t
nuclides (isotopes and isobars), 331t
principal characteristics, 328t
Technetium [CAS: 7440-26-8], **1597**
Tectosilicate minerals, 1013
Teflon, 622t
Teicoplanin (teichomycin complex), producing organism, 118t
Tektite, **1597**
Tellurium
abundance, 330t
covalent radius, 344t
electronic structure, 336t
interatomic distance, 342t
ionic crystal radius, 341t
nuclides (isotopes and isobars), 331t
principal characteristics, 328t
Tellurium [CAS: 13494-80-9], **1597–1598**
Tellurium-copper, 439t
Telomerization reactions, **1598**
Telomycin, activity and producing organism, 128t
Temperature, **1598**
Temperature scales and standards, **1598–1599**
Temperature-swing adsorption, 40
Temperature transfer standard, **1599**
Tenacity, **1599**
Tencel, 622t
Teniposide, topoisomerase interactive, 357t
Tenorite, **1599**
Tensile strength, **1599–1600**
Tensiometer, **1600**
Tension test, **1600**
Tentoxin, activity and producing organism, 128t
Tera, 1643t
Terbacil, environmental health advisories, 771t
Terbium
abundance, 330t
electronic structure, 336t
interatomic distance, 342t
ionic crystal radius, 341t
nuclides (isotopes and isobars), 331t
principal characteristics, 328t
properties, 1421t, 1422t
Terbium [CAS: 7440-27-9], **1600–1601**
Terbutryn, environmental health advisories, 771t
Terephthalic acid [CAS: 100-21-0], **1601**
Ternary alloy, 56
Ternary critical point, **450**
Terpene alcohol, **1601**
Terpeneless oil, **1601**
Terpenes, **1601–1602**
biodegradable, 207t
Terpenoids, **1601–1602**
Terphenyls, **236–237**
Terramycin, year of discovery, 130t
Tertiary alcohols, 46
Tertiary amides, 74
Tertiary amines, 74, 75
Teslac, hormonal therapy, 358t
Tesla (T), 1645t
Testicular feminization, genetic influence, 716
Testing (Chemical), **1602**
Testing (Physical), **1602–1603**
Testing (Physiological), **1603**
Testis, 98
Testolactone USP, hormonal therapy, 358t
Testosterone, 98, 99
where produced, structure, and principal functions, 789t
Tetrabromo-bisphenol, flame retardant, 640t
Tetrabromobisphenol A, flame retardant, 640t
Tetrabromo-bisphenol A, flame retardant, 640t
Tetrabromo-bisphenol A carbonate oligomer, phenoxy end capped, flame retardant, 640t
Tetrabromocy-clooctane, flame retardant, 640t
Tetrabromodipentaerythritol, flame retardant, 640t
Tetra(*tert*-butylperoxy)silane, physical properties, 1232t
Tetra-4-*tert*-butyl-10-phthalocyaninato silicon dichloride, Langmuir-Blodgett films made from, 1018
Tetracaine, 100t
2,3,5,6-Tetrachloro-1,4-benzoquinone, physical properties, 1402t
3,4,5,6-Tetrachloro-1,2-benzoquinone, physical properties, 1402t
Tetracycline, year of discovery, 130t
Tetracycline antibiotics, **129–131**
Tetradecabromo-diphenoxybenzene, flame retardant, 640t
Tetradecane, physical properties, 47t
Tetradecanedioic acid, physical properties, 490t
Tetradecanol, physical properties, 47t
1-Tetradecene, physical properties, 1150t

Tourmaline, **1625-1626**
  hardness, 1008t
  irradiation, 709t
Townsend avalanche, **1626**
Toxaphene insecticide, in hazardous waste, 1711t
Toxicity, **1626**
Toxicology, **1626**
Toxic spoil, 1439t
Toxic Substances Control Act, 1711t
Toxline, 769t
Toxnet, 769t
Trace and residue analysis, **1626-1628**
Trace element (Micronutrient), **1628**
Trace mineral nutrients, 1001-1005, 1002t
Tracer, **1628-1629**
Tracer compound, 429
Trachyte, **1629**
Tragacanth gum, 748t
Transactinides, 23, 24, 332-334
  principal characteristics of elements, 328t
Transactinium earths, **1629**
Transaldolase, 283
Transferases, 571t
Transference number, **1629**
Transfer magnetoresistance, 752
Transferrin, source and function, 986t
Transfer RNA, 713-714, 1125
Transition element, **1629**
Transition metal, **1629**
Transition temperature, **1629**
Transketolase, 283
Transmissible mink encephalopathy, 1696
Transmutation, **1629**
Transport number, **1629**
Transport proteins, 1374
Transuranium elements, **1629**
Trapped ions, **1629**
Travertine, **1629**
Tray and compartment dryers, 509t
Tray dryers, 509t
Tree fruits, susceptibility to iron deficiency, 874t
Tremolite, 27, 149-150
  physical and chemical properties, 150t
Tremolite [CAS: 1332-21-4], **1629**
Trevira, 623t
Trexan, 93t
Triacetyloleandomycin, commercial products, 121t
Triallate, environmental health advisories, 771t
Triamcinolone, commercial microbial transformations used to produce, 1550t
Tribasic acids, 13
Triboluminescence, 946t
Tribomoneopentyl alcohol, flame retardant, 640t
2,4,6-Tribromophenol, flame retardant, 640t
Tribromophenyl allyl ether, flame retardant, 640t
Tribromostyrene, flame retardant, 640t
Tri (*tert*-butylperoxy)borane, physical properties, 1232t
Tricalcium phosphate, 269
Tricarboxylic acid cycle, 1596-1597
Tricarcillin, year of discovery/market introduction, 106t
1,3,5-Trichlorobenzene, dye carrier, 512t
Trichloroethylene, 100t
2,2,2-Trichloro-1-hydroxyethyl hydroperoxide, 1233t
Trickling filters, 1725

Triclinic crystal system, crystallographic elements, 455t
Triclopyr, environmental health advisories, 771t
ω-Tricosenoic acid, Langmuir-Blodgett films made from, 1018
Tridecanedioic acid, physical properties, 490t
1-Tridecene, physical properties, 1150t
Tridymite, **1629**
  crystal structure, 455
Trienomycins, biological activity, 108t
Triethanolamine, 587
Triethylenediamine, physical properties, 483t
Triethylene glycol, physical properties, 590t
Triethylenetetramine, physical properties, 483t
Triethylgallium, 702
3,6,9-Triethyl-3,6,9-trimethyl-1,2,4,5,7,8-hexoxononane, 1234t
Trifluoromethanesulfonic acid, physical properties, 1568t
Trifluralin, environmental health advisories, 771t
Triglycerides, target of medical diagnostic test, 975t
Trigonal crystal system, crystallographic elements, 455t
Trihydric alcohol, 46
Trilobine, 49t
Trim cooler, 760
Trimethylcarbinol, 7
3,3,5-Trimethylcyclohexanone, physical properties, 900t
3,5,5-Trimethyl-2-cyclohexen-1-one, physical properties, 900t
3,5,5-Trimethyl-3-cyclohexen-1-one, physical properties, 900t
Trimethylene glycol, 46
Trimethylgallium, 702
2,6,8-Trimethyl-4-nonanone, physical properties, 900t
Trimethylolethane, polyol for alkyd synthesis, 53t
Trimethylolpropane, polyol for alkyd synthesis, 53t
Trimethylolpropane adduct, commercial polyether polyol, 1654t
1,2,7-Trimethyl xanthine, 50
Trimetrexate, antimetabolite, 355t
1,3,5-Trinitrobenzene, 1082
  pH range and color change of indicator, 825t
2,4,7-Trinitrofluorenone, sensitizer for semiconductors, 535t
2,4,6-Trinitrophenol, physical properties, 1081t
Trinitrotoluene (TNT), physical properties, 1081t
1,2,4-Trioxolane, boiling point, 1235t
1,1,3-Triphenylguanidine, 747t
1,2,3-Triphenylguanidine, 747t
Triphenylmethane and related dyes, **1629–1631**
Triphosphoric monoester hydrolases, 571t
Triphylite, **1631**
Triple bond, **1631**
Triple bonds, 346
Triple point, **1631**
Tripoli, abrasive properties, 745t
Tripolite, **1631**
Trisaccharides, 279t
Tris-dibromopropylisocyanurate, flame retardant, 640t
Trisilanyl, 1477
Trisilanylene, 1477
Trisodium phosphate, 1492
Triterpenoids, 1601
Tritium, **1631**
Trivial name, **1631**
tRNA, 713–714, 1125
Troctolite, 701
Tropine, 49t
Tropine alkaloids, 49t
Troposphere, 156
Trypsin, therapeutic enzyme, 574t
Tryptophan
  first isolation and isoelectric point, 78t
  manufacture, 76t
  in selected foods, 75t
  structural classification, 79t
L-Tryptophanase, therapeutic enzyme, 574t
Tuberactinomycin N, activity and producing organism, 128t
Tukon hardness scale, 756
Tung oil, 1671
  fatty acid composition, 507t
Tungstate minerals, 1012
Tungsten
  abundance, 330t, 1132t
  covalent radius, 344t
  electronic structure, 337t
  interatomic distance, 342t
  ionic crystal radius, 341t
  nuclides (isotopes and isobars), 331t
  physical properties of high temperature, 774t
  principal characteristics, 328t
  properties of refractory, 1075t
Tungsten blues, 1633
Tungsten carbide, 1632
  hardness, 755t
  plasma synthesis, 318t
Tungsten [CAS: 7440-33-7], **1631–1633**
Tunnel dryers, 509t
Turbidimetry, **1633**
Turbulent flow, **1633–1634**
Turquoise, **1633–1634**
Twinning (Crystal), **1634**
Twitchell process, **1634**
Twitchell's reagent, **1634**
Tylenol, 93t
Tyndall, John (1820–1839), **1634**
Tyndall cone, 1636
Tyndall effect, **1634**
Type metals, antimony content, 139t
Tyril-880, 21t
Tyrocidines, activity and producing organism, 128t
Tyrosinase
  metal chelate enzyme, 323t
  source and function, 986t
L-Tyrosinase, therapeutic enzyme, 574t
Tyrosine
  first isolation and isoelectric point, 78t
  manufacture, 76t
  in selected foods, 75t
  structural classification, 79t
Tyrosine kinase receptors, 1272
Tyrosinemia, genetic influence, 716
Tyrothricin
  activity and producing organism, 128t
  year of discovery/market introduction, 106t
Tyuyanunite, **1634**

U
^{234}U, 1646
^{235}U, 1646, 1649–1650
^{238}U, 1646, 1649–1650
U73,975, DNA interactive agent, 357t
Ugrandite, **1635**
Uintahite, **1635**
UK-68,597, producing organism, 118t
UK-69,753, formula and producing organism, 116t
UK-72,051, producing organism, 118t
Ulexite, **1635**
Ulmin, **1635**
Ultimate analysis, 97
Ultisols, 1497t
Ultraaccelerators, 5
Ultrabasic, **1635**
Ultracentifuge, **1635**
Ultracentrifuge, 315–316
Ultrafiltration, **1635–1636**
Ultrahigh molecular weight polyethylene, 1140t
Ultrahigh-strength steels, 58
Ultrahigh vacuum, 1661t
Ultramicroscope, **1636**
Ultrasonic density sensors, 1637–1638
Ultrasonic level detectors, 1638
Ultrasonic nondestructive characterization, 1638
Ultrasonic nondestructive testing, 1092–1093
Ultrasonic pressure transducers, 1638
Ultrasonics, **1637–1639**
Ultrasonic speech, human perception, 1639
Ultrasonic thermometers, 1638
Ultratrace mineral nutrients, 1001–1005, 1002t
Ultraviolet catastrophe, 1393
Ultraviolet film, 1293–1294
Ultraviolet radiation, **1639–1640**
Ultraviolet spectrometers, **1640–1641**
Ultraviolet stabilizers, **1641–1642**
Uncertainty principle, **1642**
Undecanedioic acid, physical properties, 490t
1-Undecene, physical properties, 1150t
Underground storage of products and wastes, 1729–1730
United States-Canada Air Quality Agreement, 11
Units and standards, **1642–1645**
Universal-pressure boiler water treatment, 1745–1746
Unphenelfamycin, formula and producing organism, 116t
Unresisted expansion, 34
Unsaturated compound, 429
Unsaturated fats, 1671
Unsaturated fatty acids, 1671t
UOP Sorbex, 41
Up quark, 1397
Upsilon particle, **1645–1646**
Uralite, **1646**
Urandium-radium series, 332
Uranine (CI 45350), 1756
Uraninite, **1646**
Uranium, 23t
  abundance, 330t, 1132t
  active deposit, 29
  binary compound properties, 25–26t
  electronic structure, 337t
  interatomic distance, 342t
  ionic crystal radius, 341t
  isotope separation, 1649–1650
  oxidation states, 24t
  physical properties, 24t
  principal characteristics, 328t
  purification, 863t
Uranium carbides, 1648
Uranium [CAS: 7440-61-1], **1646–1650**
Uranium chlorides, 1649
Uranium enrichment, **566,** 1649–1650
Uranium hexafluoride, 1649
Uranium oxides, 1648
Uranium spent-fuel reprocessing, 1647
Uranyl peroxide, 1648
Urate, target of medical diagnostic test, 975t
Urea
  constituent of human blood, 242t
  in 24 hour urine sample, 1657t

as parent structure compound, 1090t
target of medical diagnostic test, 975t
Urea-ammonium orpthophosphate, **1652**
Urea-ammonium polyphosphate, **1652**
Urea [CAS: 57-13-6], **1650–1652**
Urea cycle abnormalities, genetic influence, 716
Ureaform, **1652–1653**
Urea-formaldehyde resin, production methods for cellular, 664t
Urea-formaldehyde resins, **1653**
Urease, **1653**
Urech cyanohydrin method, **1653**
Urech hydantoin synthesis, **1653**
Urena, 632t
Urethane [CAS: 51-79-6], **1653**
Urethane polymers, **1653–1656**
Urethane sealants, 1462
Urey, Harold C. (1894–1981), **1656**
Uric acid
constituent of human blood, 242t
in 24 hour urine sample, 1657t
and purine metabolism, 1382
Uricase, metal chelate enzyme, 323t
Urine, **1656–1657**
Urokinase, therapeutic enzyme, 574t
Uronic acid, **1657**
Uteracon, where produced, structure, and principal functions, 788t
Uvarovite, 705, 1635

V

Vaccine technology, **1659–1661**
Vacuum, **1661–1665**
Vacuum carburizing, 763t
Vacuum deposition, **1665**
Vacuum distillation, **1665**
Vacuum electronics, 1017
Vacuum flasher, 1255
Vacuum measurement, 1663–1665
Vacuum pumps, 1662–1663
Vacuum rotary dryers, 509t
Vacuum tray dryers, 509t
Valence, 345–346, **1665**
Valine
first isolation and isoelectric point, 77t
manufacture, 76t
in selected foods, 75t
structural classification, 79t
synthesis from products of carbohydrate metabolism, 282t
Valinomycin, activity and producing organism, 128t
Vanadate minerals, 1012
Vanadinite, **1665**
Vanadium
abundance, 330t, 1132t
biologically active chelates, 323t
covalent radius, 344t
electronic structure, 336t
interatomic distance, 342t
ionic crystal radius, 341t
nuclides (isotopes and isobars), 331t
physical properties of high temperature, 774t
principal characteristics, 328t
in representative U.S. crude oils, 1242t
in representative world crude oils, 1243t
trace mineral nutrient, 1002t, 1005
Vanadium [CAS: 7440-62-2], **1665–1667**
Vanadium hydride, physical properties, 796t
Vanadium nitride, plasma synthesis, 318t
Vancomycin, producing organism, 118t
Van Der Waals, Johannes Diderik (1837–1923), **1668**
Van der waals equation, **1667–1668**
Van der waals forces, **1668**
Van der Waals radius, 340
Vanillin [CAS: 121-35-5], **1668–1669**
Vanillin sugar, 1669
Van't Hoff, Jacobus Hendricus (1852–1911), **1669**
Van't Hoff equation, **1669**
Van't Hoff law, **1669**
Vapor, **1669–1670**
Vapor density, **1670**
Vapor heat exchanger, 760
Vaporization, **1670**
Vaporization (Heat of), **1670**
Vapor pressure, **1670**
Variable (Process), **1670**
Varicella vaccine, 1659
Variolite, **1670**
Varnish, **1670–1671**
Var (var), 1645t
Vasicine, 49t
Vasoconstrictine, where produced, structure, and principal functions, 786t
Vasophysin, where produced, structure, and principal functions, 789t
Vasopressin, where produced, structure, and principal functions, 789t
Vasotonin, where produced, structure, and principal functions, 786t
Vat dyes, 512t, 517–518
applications, 519
dyeing process, 521–522
Vegetable fibers, **631–633**
Vegetable oils (Edible), **1671–1674**
Vegetables, susceptibility to iron deficiency, 874t
Vegetable waxes, 1746–1747
Velban, tubulin interactive, 358t
Vepesid, topoisomerase interactive, 357t
Verdigris, 6
Verdoflavin, 1699
Vermiculite, insulation material, 857
Vernolate, environmental health advisories, 771t
Vertisols, 1497t
Very high vacuum, 1661t
Very large scale integration, 1017
Very low density polyethylene, 1140t
Vesuvianite, **1674**
Vetiver oil, 647t
Vibramycin, year of discovery, 130t
Vibrating-tray dryers, 509t
Vibratory feeder, **605**
Vibrio comma, gram-negative, 168t
Vicalloy II, thin-film applications, 958t
Vickers hardness scale, 756
Vinblastin sulfate USP, tubulin interactive, 358t
Vincristin sulfate USP, tubulin interactive, 358t
Vindesine sulfate, tubulin interactive, 358t
Vinegar, **1674–1675**
Vinegar acid, 6
Vineger eels, 1675
Vinorelbine, tubulin interactive, 358t
Vinyl acetal polymers, **1675–1676**
Vinyl acetate
physical properties, 585t, 1677t
polymerization, 1676–1678
Vinyl acetate polymers, **1676–1678**
Vinyl alcohol-methyl methacrylate copolymers, 1679
Vinyl alcohol polymers, **1678–1679**
N-Vinylamide polymers, **1680–1682**
N-Vinylamides, preparation, 1680
Vinylcaprolactam, 1680
Vinyl chloride
definitely established workplace carcinogen, 297t
physical properties, 366t
Vinyl chloride-acrylonitrile copolymers, ultrafiltration media application, 1635
Vinyl chloride [CAS: 75-01-4], **1682–1685**
Vinyl chloride polymers, **1685–1688**
Vinyl cyanide, 20
Vinyl ester polymers, **1687–1689**
Vinyl ether monomers and polymers, **1689–1690**
Vinyl ethers, polymerization, 1689–1690
Vinyl formamide, 1680
Vinylidene chloride, physical properties, 1691t
Vinylidene chloride copolymers
diffusion and solubility coefficients for oxygen and carbon dioxide, 173t
gas permeability, 172t
permeation of flavor/aroma compounds, 174t
water-vapor transmission rate, 173t
Vinylidene chloride monomer and polymers, **1691–1693**
Vinylidene cyanide, monomer reactivity and suitable initiator for, 838t
N-Vinylimides, preparation, 1680
Vinyl ketones, monomer reactivity and suitable initiator for, 838t
N-Vinyllactams, 1680
Vinyl polymerization, 1181, 1341
Vinylpyrrolidinone, 1680
N-Vinyl-2-pyrrolidinone, preparation, 1680
Vinyl resins, alkyd resins with, 54
Vinyltoluene, 1625
Viral replication, 1694
Viral vaccination, 1696–1697
Virginiamycin M_1, activity and producing organism, 128t
Viridogrisein, activity and producing organism, 128t
Virion, 1693
Virtanen, Arrturi I. (1895–1973), **1693**
Virus, **1693–1697**
Viscoelasticity, **1697**
Viscometer (or Viscosimeter), **1697**
Viscose process, **1697**
Viscose rayon, fiber-dye property requirements, 521t
Viscosimeter, 1697
Viscosity, **1697**
Viscosity measurement, 1443
Visible spectrochemical analysis, **1531**
Vitamin, **1697–1698**
Vitamin A, 1697, **1697–1699**
constituent of human blood, 242t
loss from food operations, 1698t
Vitamin B_1, 1610–1611, 1697
loss from food operations, 1698t
Vitamin B2, 1697
loss from food operations, 1698t
Vitamin B_2 (Riboflavin), **1699–1700**
Vitamin B6, 1697
Vitamin B_6 (Pyridoxine), **1700–1701**
Vitamin B_{12}, 1697
constituent of human blood, 242t
Vitamin B_{12} (Cobalamin), **1701–1703**
Vitamin B complex, 1697
Vitamin C, **151–152,** 756
loss from food operations, 1698t
Vitamin D, 1697, **1703–1704**
in milk, 1001
Vitamin D_2, constituent of human blood, 242t
Vitamin D-resistant rickets, genetic influence, 716
Vitamin E, 1697, **1705–1706**
constituent of human blood, 242t
Vitamine, 1697

Vitamin G, 1699
Vitamin K, 1697, **1706–1707**
Vitamins
  loss in food processing, 1697–1698, 1698t
  relationship of hormones to, 786–789t

Wöhler synthesis, **1750**
Wohlwill process, **1750**
Wolffenstein-Boters reaction, **1750**
Wolff-Kishner reaction, **1750**
Wolff rearrangement, **1750**
Wolframite, **1750–1751**
Wollastonite, **1751**
Wood, **1751**
  excess air for combustion, 426t
Wood burning, 1718
Wood dust, definitely established workplace carcinogen, 297t
Woodell's hardness scale, 2t
Wood fiber, insulation material, 857
Wood preservative, **1751–1752**
Wood pulp production and processing, **1379–1382**
Wood's metal, 923t
  bismuth in, 238t
Woodward, Robert B. (1917–1979), **1752**
Woodward-Hoffmann rules, **1752**
Wool, **1752**
  dyeing, 522
  fiber-dye property requirements, 521t
  generic designation and definition, 624t
  physical properties of staple, 626t
Wool-acrylic fiber blends, dyeing, 525
Wool-cellulosic fiber blends, dyeing, 525
Wool-nylon fiber blends, dyeing, 525
Wool-polyester fiber blends, dyeing, 525
Woolwax, 1747
Wrought ferrous metals, 58
Wrought iron, **1752**
Wrought nickel, 1071t
Wulfenite, **1752–1753**
Würtz-Fittig-Frankland reaction, **1753**
Wurtzite, **1753**
Wurzite, crystal structure, 455

X
Xalstocite, **1755**
Xanthan gum, **1755**
Xanthates, **1755–1756**
Xanthene dyes, **1756**
Xanthic acids, 1755
Xanthine oxidase
  metal chelate enzyme, 323t
  source and function, 986t
Xanthylium, 1756
Xenoblast, **1757**
Xenocryst, **1757**
Xenolith, **1757**
Xenomorphic, **1757**
Xenon
  abundance, 330t, 1132t
  electronic structure, 336t
  nuclides (isotopes and isobars), 331t
  percentage in air, 46t
  principal characteristics, 328t
Xenon 133, 1757
Xenon 135, 1757
Xenon [CAS: 7440-63-3], **1757**
Xenon platinum hexafluoride, 1757
Xenon tetrafluoride, 1757
Xenotime, 1771
Xenotropic, **1757**
Xi particle, **1758**
X-ray, **1758**
X-ray analysis, **1758–1761**
X-Ray analyzer, electron-microprobe, 1759–1760
X-ray cat scanner (CAT), 1761–1762
X-ray computed tomography, 1092
X-ray crystallography, 1759
X-ray detectors, 1759, 1760
X-ray fluorescence analysis, 1760–1761
X-ray generation, 1759
X-rays, gemstone irradiation, 708t
X-ray scan and other medical imagery, **1761–1763**
X-ray spectral lines, 1758–1759
Xylem, 1751
Xylene
  biodegradable, 207t
  combustion constants, 422t
  from toluene, 1625
m-Xylene
  manufacture, 1765–1766
  physical properties, 1763t, 1766t
o-Xylene
  manufacture, 1765–1766
  physical properties, 1763t, 1766t
p-Xylene
  liquid-phase adsorption, 41
  manufacture, 1765–1766
  physical properties, 1763t, 1766t
Xylene [CAS: 1330-20-7], **1763**
Xylene isomerization, 1766
Xylene polymers, **1763–1765**

Xylenes and ethylbenzene, **1765–1766**
p-Xylylene (PX), 1763–1765

Y

YAG and YIG, **1767**
Yard waste, in municipal waste, 1714t
Yeasts and molds, **1767–1770**
Yellow brass, 440t
    hardness of annealed and cold-rolled, 755t
Yellow fever virus, 1694
Yellow gold, 736
Yellow quark, 1397
Yield strength, 784
Ylang ylang, 647t
Yohimbine, 49t
Ytterbium
    abundance, 330t
    electronic structure, 337t
    interatomic distance, 342t
    ionic crystal radius, 341t
    nuclides (isotopes and isobars), 331t
    principal characteristics, 328t
    properties, 1421t, 1422t
Ytterbium [CAS: 7440-64-4], **1770**
Ytterbium orthoferrite, 1770
Yttrium
    abundance, 330t, 1132t
    covalent radius, 344t
    electronic structure, 336t
    interatomic distance, 342t
    ionic crystal radius, 341t
    nuclides (isotopes and isobars), 331t
    principal characteristics, 328t
    properties, 1421t, 1422t
Yttrium aluminum garnet (YAG), 1767, 1771
Yttrium carbide, 1771
Yttrium [CAS: 7440-65-5], **1770–1771**
Yttrium halides, 1771
Yttrium hydroxide, 1771
Yttrium iron garnet (YIG), 1767, 1771
Yttrium nitrate, 1771
Yttrium oxalate, 1185
Yttrium oxide, 1771
Yttrium peroxide, 1771

Z

Zanosar, DNA alkylating/cross-linking agent, 356t
Zeeman, Erik Christopher (1925–), **1773**
Zeeman effect, **1773**
Zeisberg concentrator, **1773**
Zeisel reaction, **1773**
Zeolite A
    composition, 1034t
    pore structure, 41t
    preparation, 1035t
Zeolite group, **1773**
Zeolite L
    composition, 1034t
    pore structure, 41t
Zeolite minerals, 1034
Zeolite omega
    composition, 1034t
    preparation, 1035t
Zeolites, 65, 1033–1036
    for gas adsorption, 39t
    for liquid adsorption, 41t
    for liquid-phase adsorption, 41
Zeolite X
    composition, 1034t
    preparation, 1035t
Zeolite Y
    composition, 1034t
    preparation, 1035t
Zeolite ZSM-5
    composition, 1034t
    pore structure, 41t
    preparation, 1035t
Zerevitinov determination, **1773**
Zero-order reaction, **1773**
Zero point energy, **1773**
Zeroth law of thermodynamics, 1605–1606
Zeta potential, **1773**
    role in dyeing, 520
Ziegler, Karl (1898–1973), **1774**
Ziegler catalyst, **1773–1774**
Ziegler method, **1774**
Ziegler-Natta catalysts, 1148–1149
Ziegler-Natta polymerization, **1774**
Ziegler process, 1774
Zimmermann reaction, **1774**
Zinc
    abundance, 330t, 1132t
    biologically active chelates, 323t
    constituent of human plasma or serum, 244t
    corrosion resistant alloys, 446t
    covalent radius, 344t
    electronic structure, 336t
    interatomic distance, 342t
    ionic crystal radius, 341t
    nuclides (isotopes and isobars), 331t
    plant micronutrient, 613t
    plant micronutrient deficiencies, soils of U.S., 616t
    principal characteristics, 328t
Zinc acetate, 6
Zinc-air cell, 184–185, 189
Zinc alloys, 58
Zinc arsenate, wood preservative, 1752
Zincblende, crystal structure, 455
Zinc-bromine cell, 183
    cell reactions and energy content (in development), 180t
Zinc [CAS: 7440-66-6], **1774–1776**
    major sources of industrial minerals, 1011t
    standard electrode potential, 31t
    trace mineral nutrient, 1002t, 1004
    water quality indicator, 1726
Zinc chloride, wood preservative, 1752
Zinc chloride cell, cell reactions, energy content, and manufacturers, 179t
Zinc-chlorine cell, 183
Zinc coating, 1775
Zinc cyanide, EPA pretreatment standard for aqueous discharge, 985t
Zinc die-casting alloys, 1775–1776
Zinc electroplating, 557t
Zinc fluoride, 1776
Zinc hydroxide, 1776
Zinc (In Biological Systems), **1777–1778**
Zincite, **1778**
Zinc-manganese dioxide cell, 184t
Zinc-mercuric oxide cell, 184
Zinc metalloenzymes, 1777–1778
Zinc nitride, 1776
Zinc oxide, 1776
    plasma synthesis, 318t
Zinc oxycarbonate, 1776
Zinc-oxygen cell, 189
Zinc peroxide, 1776
Zinc phosphide, 1776
Zinc poisoning, 1778
Zinc selenide, 1776
Zinc-silver oxide cell, 184t
Zinc spinel, 701
Zinc spraying, 703
Zinc stearate, as release agent, 1435t
Zinc sulfide, 1776
Zinc telluride, 1776
Zinostatin, activity and producing organism, 128t
Zircon, **1778**
    heat effect, 708t
    physical properties, 1428t
Zirconia, dielectric permittivity, 852t
Zirconium
    abundance, 330t
    corrosion resistant alloys, 446t
    covalent radius, 344t
    electronic structure, 336t
    interatomic distance, 342t
    ionic crystal radius, 341t
    nuclides (isotopes and isobars), 331t
    principal characteristics, 328t
Zirconium [CAS: 7440-67-7], **1778–1779**
Zirconium dioxide, plasma synthesis, 318t
Zirconium hexafluoride, 1779
Zirconium nitride, 1779
    plasma synthesis, 318t
Zirconium oxide, 1779
Zircon porcelain, **1358**
Zoisite, **1779**
    heat effect, 708t
Zoladex, hormonal therapy, 358t
Zone refining, **1779–1780**
Zsigmondy, Richard (1865–1929), **1780**
Zsigmondy reagent, **1780**
Zwitterion, **1780**
Zymolytic reaction, **1780**
